The inhalational anesthetic agents are liquids at room temperature. A special delivery device called a vaporizer is required to deliver an accurate supply of the vapor. All vaporizers have several features in common. They provide a reservoir of the inhalational liquid with a level indicator and are capable of delivering a constant level of vaporization. Most newer vaporizers also have a color-coded keyed filler (eg, purple for isoflurane and yellow for sevoflurane) that prevents the accidental filling of the vaporizer with the wrong agent. This error could result in overdosing the patient because the vaporizer calibration is drug specific. If two vaporizers are accommodated in series on the anesthesia machine back bar, then an interlocking system should be used to prevent the accidental use of both vaporizers. Otherwise, the results would be contamination of the second vaporizer by gas from the first vaporizer and an uncontrolled excess delivery of gas to the patient.

One of the main problems with using these inhalational agents in the PICU is how to deliver them to the patient. One technique is to use an anesthesia machine to deliver the gas to an ICU ventilator with the correct oxygen percentage and inhalational agent. This mixture is delivered from the fresh gas outlet of the anesthesia machine. It is selected by adjustment of the flow rotameters on the anesthesia machine to give the desired oxygen concentration and then selection of the desired inspired concentration of inhalational agent on the vaporizer. Unfortunately, most ICU ventilators will not accept this low-pressure gas supply as their driving gas. The Servo 900C is an exception because it has a low-pressure inlet option for the driving gas. High flow rates are required to maintain filling of the bellows of the ventilator; the flow rates must be higher than the minute ventilation. This requirement sometimes limits the inspired oxygen because the maximum flow of oxygen from the rotameters of the anesthesia machine is 10 to 12 L/m. Also, this process consumes a lot of vapor.

Also available is another Servo ventilator, the 900D, which has a custom-fit vaporizer on the normal high-pressure input. This machine is similar to the 900C, but it has been modified for anesthesia use and allows hand ventilation with inhalational agents. Maquet now offers an ICU type ventilator that delivers inhalational anesthesia, the Flow-I machine. It uses proprietary vaporizers and has a circle system to reduce fresh gas flow. Due to the recirculating nature of the circuit, gases and inhalational monitoring are mandatory. If the fresh gas is too low, then the circuit could become hypoxic; if the CO_2 absorbents have an issue, then hypercapnia can be a concern. Also the end-tidal inhalational agent needs to be monitored to ensure that it is clinically appropriate and that the vaporizers are functioning properly. Often the only alternative is to deliver anesthetic with an anesthesia machine. Anesthesia machine ventilators are not as sophisticated as ICU ventilators, may not be able to deliver appropriate volumes for pediatric patients, and often have limited positive end-expiratory pressure capabilities. The anesthesia machine needs to be checked before use and its correct function should be continually assessed during its use, which requires an understanding of the setup and alarms on the machine and an understanding of the procedures of the appropriate tests. This understanding usually is not within the confines of a pediatric intensivist's scope of practice, and an anesthesiologist should be involved to ensure the safe and effective use of this apparatus.

Whenever inhalational agents are used, the waste gases from the expiratory limb of the ventilator should be scavenged to avoid prolonged exposure of the health care

worker to these agents. The Occupational Safety and Health Administration limits occupational exposure to 2 ppm halogenated volatile agents for health care workers.[245] The worker is at risk of becoming sedated, and potential teratogenic effects also exist. Several large studies about prolonged exposure to these agents have not shown any increase in risks for anesthesia personnel with respect to hepatic disease, teratogenesis, spontaneous abortions, psychologic difficulties, infertility, neuropathy, or bone marrow depression.[246] Caution also should be taken when filling the vaporizer to avoid spilling the liquid during the process.[247] Two forms of scavenging are available. A passive system involves simply a tube connected to the expiratory limb connected to the outside. This system is at risk of occlusion because of kinking or someone standing inadvertently on the tubing, which will then occlude the expiratory limb of the ventilator. An active system involves an active suction to the expiratory limb, with a safety reservoir bag in series to prevent the patient from being exposed to excess suction pressure.

In the operating room it is routine to monitor the levels of anesthesia agents given with a gas analyzer. This monitoring provides an inspired and expired inhalational agent concentration and is helpful to ensure that the vaporizer is functioning correctly, that the vaporizer has not emptied without being detected, and that the concentration dialed on the vaporizer has reached its effect. When the end-tidal inhalational agent concentration equals the inspired agent, then steady state has been achieved. This steady state normally occurs rapidly with isoflurane, but in a patient with severe asthma due to the severe limitation in airflow gas exchange, achievement of steady state may be delayed.

If the PICU staff is unfamiliar with the delivery system being used for the isoflurane, then it would be appropriate to have staff from the anesthesiology department set up the equipment and ensure that it functions correctly. Failure to configure the delivery system correctly has the potential to cause considerable harm or death. Once the situation has stabilized, an anesthesiologist may not be required at the bedside. However, an anesthesiologist should be available by pager to help troubleshoot any difficulties. In these cases the inspired agent should be monitored continually.

The use of inhalational agents in the PICU involves the use of equipment that may be unfamiliar to pediatric intensive care physicians. Isoflurane appears to be the best choice,[248] and it offers several useful advantages, including the ability to deeply sedate patients (especially those difficult to sedate) without polypharmacy.[249] Although they are currently poorly defined,[250] tolerance and a withdrawal-like syndrome have been described; however, they appear to occur more slowly than with other sedative agents. It may be helpful to have a set of guidelines available for isoflurane use to facilitate its use in the PICU. These guidelines could include equipment use, monitoring requirements, dosing, and treatment of complications.[251] Caution should be used in patients who may have raised ICP because isoflurane may increase CBF. Isoflurane does allow for rapid arousal if neurologic examinations are required.

The anesthetic conserving device (AnaConDa) is a modified heat moisture exchanger that has been developed to allow the use of inhalational agents in the ICU without requiring high fresh gas flows or specialized ventilators.[252] It is placed in the breathing circuit between the ventilator Y circuit and the endotracheal tube. The liquid anesthesia agent is injected directly into the device using a syringe pump. The

device membrane allows for the inhalational agent to be taken up by the inspired gas. On expiration, much of the inhalational agent is deposited on the membrane, allowing for an efficient inhalational rebreathing technique. The inhalational consumption has been shown to be equivalent to that of the conventional circle system.[253] The inspired concentration of the inhalational agent is monitored from the device using a routine gas analyzer. There are quite a few reports of its use in adult ICU from Europe as well as two pediatric studies. In adults there was a decrease in postoperative mortality in those patients receiving isoflurane instead of midazolam/propofol.[254] All patients received sedation for more than 96 hours. It has also been used for postoperative adult cardiac patients[255]; the patients received the same postoperative sedation as they received for their general anesthetic technique. Patients receiving the inhalational sedation were ready for extubation and extubated more rapidly than those in the propofol group. The inhalational group in the ICU had more vasodilation and required more vasopressor support. The use of isoflurane proved to be effective and not difficult to use in the ICU; however, there was no difference in outcome, length of stay, or quality of sedation. In conjunction with this study, the researchers also evaluated a method for scavenging the exhaled isoflurane.[256] A Deltasorb canister was used between the patient expiratory limb and the reservoir bag, which vented to the wall suction. The canister contains a hydrophobic matrix that acts as a molecular sieve and selectively captures volatile agents from the gas mixture.

A similar concept is now used when preparing an anesthesia workstation for a patient at risk for malignant hyperthermia. In this case the volatile agent is scavenged from the circuit so that the patient is not exposed to any volatile material that has dissolved into the machine components. This is based on an activated charcoal filter and has a limited duration of effect.[257] Some problems due to excess dosing have been experienced, and the 100-mL dead space of the device, as well as resistance to gas flow, may make its use inappropriate in children. A report of 7 days of isoflurane delivery using the AnaConDa device in children demonstrated that effective sedation was possible in 4 hours; other sedatives were able to be weaned.[258]

Compared with an inhalational agent vaporizer, there is no percentage inhalational agent dial. The rate on syringe injection determines the percentage of the inhalational agent. This infusion rate is set according at a prerecommended rate. Initially the inspired concentration is low because of dilution. Differences in minute ventilation and gas flows may make this prerecommended rate inaccurate. The injection rate needs to be titrated to the monitored percentage of the inspired inhalational agent, which can increase significantly with time, especially until equilibrium is reached. The AnaConDa device has not been approved for use in the United States.

The use of isoflurane for sedation in conjunction with 24 hours of therapeutic hypothermia postcardiac arrest has also been reported.[259] The isoflurane sedation was chosen due to concerns about drug metabolism with hypothermia delaying neurologic assessments. Also there is some evidence that inhalational agents have a myocardial pre- and postconditioning effect, reducing the degree of reperfusion injuries. This is due to an effect on messenger kinases as well as possibly some antiinflammatory effects. Postcardiac surgery performed using inhalational anesthesia has been shown to have lower troponin levels. Postconditioning effects may also be gained in other organs including the brain. Also the inhalational agents

may facilitate a more rapid cooling by reducing shivering, lowering vasoconstrictive thresholds. Outcome was determined by the initial neurologic assessment after 24 hours of cooling.

Sedation-Related Complications

With all the advantages of sedation and analgesia in the PICU, critical care providers are becoming more aware of sedation-related adverse events. Understanding and recognizing these events are crucial prerequisites to providing the best quality care and putting forth the necessary procedures and strategies to prevent and minimize these events and their sequelae.

A multicenter study that looked at sedation-related adverse events in pediatric patients ventilated for acute respiratory failure found that a high proportion of patients had inadequate pain and sedation management. It was interesting to find that there was moderate site-to-site variability for some of the adverse events reported.[132] Clinically significant iatrogenic withdrawal, unplanned endotracheal extubation, extubation failure, postextubation stridor, and stage 2+ pressure ulcer were also reported.

Loss of sleep and sleep disruption in critically ill children in the PICU play crucial roles in short-term recovery and long-term neurocognitive outcomes. This can be attributed to the multiple physical, environmental (eg, noise), and pharmacologic factors including sedative medications.[260]

Reduced sleep can have detrimental effects, as it can lead to delirium, impaired immunity, catabolism, and respiratory insufficiency. Little is known of the effect of sedatives and analgesics on sleep in critically ill children. Benzodiazepines are believed to decrease and suppress rapid eye movement during the sleep cycle. Pediatric intensivists should have a better understanding of the physiology of normal sleep in order to differentiate between normal sleep and deep sedation in critically ill children.[260] Dexmedetomidine might have less detrimental effects on sleep compared to other more commonly used medications; further research is needed to investigate its efficacy and its effects on sleep in PICU patients. All PICUs should adopt simple maneuvers like using earplugs, eye masks, noise reduction, and light optimization to promote sleep. These maneuvers are available, noninvasive, inexpensive, and have been proved to decrease sleep interruption during nighttime hours.[261,260]

Delirium in children has been described. It was believed to be a transient problem without significant short-term or long-term neuropsychiatric consequences.[262-264] This notion has been challenged, however, and there has been an emerging literature to outline and determine the prevalence, definition, consequences and potential treatment of delirium in children, especially when they are critically ill in the PICU.

Delirium is defined as a complex neuropsychiatric syndrome characterized by disturbances of consciousness, attention, cognition, thought, language, memory, orientation, perception, the sleep-wake cycle, behavior, mood, and affect.[263-266] The *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) definition of delirium was adopted from adult studies, but it is believed that this definition can be applied in children and adolescents. Children with delirium can be irritable, cry inconsolably, be incoherent, moan, kick, and thrash. These children might not recognize family members and familiar objects.

A series of delirium-like signs were reported in the early 1960s in patients emerging for certain anesthetics like ether, ketamine, and cyclopropane, especially when they were administered for certain short procedures (eg, tonsillectomy and adenoidectomy (T&A), thyroidectomy, and circumcision).[267,265] These symptoms were reported more frequently in children than adults (12%-13% versus 5.3%). The problem of delirium has reemerged with the widespread use of inhalational anesthetic gases like sevoflurane, desflurane, and isoflurane.[262-265,268,269]

Delirium in the postanesthetic period was defined by Sikich and Lerman as "a disturbance in the child's awareness of and attention to his/her environment with disorientation and perceptual alterations including hypersensitivity to stimuli and hyperactive motor behavior."[265,270] It usually occurs within the first 30 minutes after recovery from anesthesia, can resolve spontaneously within 1 to 2 hours, but can last for up to 2 days.

The incidence of delirium in children in the PICU is unknown, but it generally is around 40% and could be up to 80%. It appears to mostly affect preschool children around 2 to 7 years old. The presence of developmental delay and the need for mechanical ventilation are risk factors associated with delirium.[262,265,266,268,271,272] There are several possible etiologies of pediatric delirium (Table 134.23).

TABLE 134.23

Etiologic Factors Related to Delirium

Anesthesia-related factors	Rapid emergence from anesthesia
Intrinsic characteristics of the anesthetic	Possible irritating side effect of inhalational anesthetics on the central nervous system
Surgery-related factors	Postoperative pain Surgery type (eg, tonsillectomy and adenoidectomy, cataract and thyroid surgery)
Patient-related factors	Age (preschool) Postoperative anxiety

It was found in many studies that the incidence of delirium in children is higher after the use of inhalational anesthetic gases, especially sevoflurane. Isoflurane and halothane were reported to cause delirium to a much lesser extent in comparison to sevoflurane. There is a lower incidence of delirium after propofol and remifentanil intravenous anesthesia.[264,265,268,269,272,273]

Many disorders can be difficult to differentiate from delirium in children. They include acute stress reaction, acute anxiety states, adjustment disorder with mixed emotions, dissociative or regressive states, and childhood-onset psychosis.[266]

The management of delirium in children has been a neglected topic in the literature, but reports have emerged that address this crucial aspect. Management should include pharmacologic and nonpharmacologic strategies. In anesthesia settings, treatment with alpha 2-adrenoceptor agonist like clonidine or dexmedetomidine has helped to reduce the incidence and frequency of postanesthetic delirium without prolonging the time to extubation or discharge.[269,273] Preoperative administration of midazolam can be useful in minimizing postanesthesia agitation by augmenting the inhibitory effects of $GABA_A$ receptors.[265] Perioperative pain management can lead to a lower incidence of delirium; different analgesic options—including ketorolac, intravenous or oral transmucosal fentanyl, oral ketamine, dexmedetomidine, and caudal block—have been recommended to eliminate pain and anxiety.[265,269,272-275] Only few reports have looked at delirium in

PICU settings; haloperidol has been used with reasonable outcomes. Initial haloperidol doses of 0.15 to 0.25 mg/dose intravenously have been used followed by a maintenance dose of 0.05 to 0.5 mg/kg per 24 hours.[262,264,266,276]

Risperidone orally has been used in less acute situations with good results. The suggested initial dose is 0.1 to 0.2 mg followed by a maintenance dose of 0.2 to 2 mg per 24 hours.[264,266,276] The use of benzodiazepines has been discouraged in the treatment of delirium in children unless it is reserved for delirium due to iatrogenic sedation withdrawal or as a possible adjunct to haloperidol for insomnia.[264,271,277]

Nonpharmacologic psychosocial strategies should be part of managing and preventing delirium in children, especially in the PICU. Interventions include parents' constant presence, comforting techniques, familiar music and photographs, toys, room lighting schedule, family-centered care, and a parent information leaflet. Appropriate pain and iatrogenic withdrawal management are very important as well.[264]

Apoptosis

Evidence from rodents suggests that most general anesthetics and sedatives, which are either *N*-methyl-D-aspartate receptor antagonists or $GABA_A$ agonists, trigger apoptosis or programmed cell death. Those incriminated include inhalational anesthetic agents (including nitrous oxide), propofol, benzodiazepines, and ketamine. Adjuvants that do not trigger apoptosis include dexmedetomidine, melatonin, opiates, and possibly xenon. Interestingly, lithium has been shown to exert an antiapoptotic effect. Massive apoptosis occurs in vulnerable regions of the brain that are responsible for learning and cognition (eg, the hippocampus, caudate/putamen, thalamus, and others) when these proapoptotic anesthetics are administered during the period of synaptogenesis or the rapid brain growth spurt in young rodents, most notably during the seventh postnatal day. The severity of the apoptosis depends on the dose of anesthetic and duration of administration. In addition to histologic changes associated with apoptosis (as evidenced by caspases-3 staining), long-term memory loss and cognitive impairment have been demonstrated.

Whether these data are directly applicable to humans has not been established. Primate research suggests that ketamine[278] induces apoptosis in vulnerable young monkeys, although an exposure to ketamine of less than 3 hours in duration does not induce significant injury. Isoflurane has also been shown to cause apoptosis in several primate studies.[279] To date, the studies in humans have been retrospective in design. Four studies have demonstrated conflicting findings on the effects of anesthetics on cognitive function in young children. The most impressive of these retrospective studies is from the twin registry in Denmark,[280] in which monozygote twins concordant or discordant for anesthetic exposure before the age of 4 years failed to demonstrate any differences in educational achievement or cognitive impairment years later. There are two ongoing prospective studies at present. Results for these studies may not be available for several years. The PANDA trial evaluates the children for neurodevelopment after 5 years post-inguinal hernia repair.[279] A prospective randomized study of general anesthesia versus regional anesthesia for lower abdominal surgery with long-term evaluation of cognitive

function in children is also currently under way (enrollment has been completed); however, 5-year neurocognitive follow-up data is still pending. These studies may help us to understand the risk, if any, of administering these general anesthetics to vulnerable human infants and young children. At present the best recommendations are that a single brief anesthetics for infants appears safe. Multiple anesthetics and surgical procedures may not be, but there are reasons aside from anesthesia for these possible complications. The evidence for anesthesia-related apoptosis in humans is weak at present, and withholding anesthesia for surgery may cause greater harm. At present there is no need to change anesthetic practice or to postpone or delay indicated surgeries for infants.[281]

Pharmacoeconomics

In today's economical climate, it is important to consider the cost of the different sedation options available to the pediatric intensivist (Table 134.24). Most PICUs use a low-cost sedative regimen for the bulk of the sedations required and keep the more expensive options for selected circumstances. Table 134.24 shows the different costs of some of the available agents in the PICU as well as the 24-hour cost for a child weighing 20 kg. They are presented as the cost per kilogram per hour of sedation at equipotent doses. They represent the lowest hospital drug cost (at the Women's and Children's Hospital of Buffalo) for each agent in its most inexpensive form and exclude preparation, delivery, and equipment issues related to each drug. Fentanyl, commonly used, is inexpensive. For a 20-kg child, it costs $13.63 per day. Midazolam is now a more inexpensive option than lorazepam. The other synthetic opiates are more expensive to use, and consideration should be given to appropriate indications for their use. A rapid recovery, however, with as quick an extubation as possible with remifentanil and early ICU discharge, is also a considerable cost factor to be considered. Propofol (which is now available in a generic form) and ketamine are both relatively inexpensive options for ICU sedation, if they are deemed clinically appropriate. The drug costs of isoflurane are comparable to those of the BZDs. Sevoflurane and desflurane remain expensive options; however, they require the availability of a specialized delivery system, which could increase the cost. If a device were available that could deliver these agents at low flows with most of the available ICU ventilators, then inhalational sedation would be a more attractive option.

TABLE 134.24

Relative Drug Costs of Different Intensive Care Unit Sedative Agents

Drug	Dose	Cost/kg/hr ($)	24-Hour Cost for 20-kg Child ($)
Morphine	50 μg/kg/h	0.01	4.80
Fentanyl	4 μg/kg/h	0.03	13.63
Sufentanil	0.8 μg/kg/h	0.03	13.82
Remifentanil	0.4 μg/kg/min	0.46	216.69
Midazolam	0.1 mg/kg/h	0.02	9.79
Lorazepam	0.1 mg/kg/h	0.05	24.48
Propofol	5 mg/kg/h	0.05	16.92
Ketamine	1 mg/kg/h	0.03	14.40
Dexmedetomidine	0.5 μg/kg/h	0.09	42.00
Isoflurane	0.5% (@ 61 L/min)	0.44	10.47
Desflurane	3% (@ 61 L/min)	35.71	857.00

Sevoflurane	1% (@ 61 L/min)	6.76	162.19
Xenon	30% (proprietary closed circuit)		392.47

When looking at the cost benefits of different sedation regimens, there are many components of the cost analysis for one to consider. It is a complex analysis that not only compares direct drug costs but needs to take into account the many factors that can influence the cost of health care. Usually length of stay in the ICU, length of hospital stay, or days of ventilation are utilized, with the calculated costs attributed to each of these parameters used to compare the sedation regimens. Other criteria may include the incidence of complications such as delirium, the cost of managing delirium, and long-term the quality of life outcome (QALYS). In addition to the economic side, there is the clinical outcome assessment to determine if there is a better outcome with one sedation method or another and to decide what is the best evidence-based medicine. The more expensive the medication, the greater the need for quality information as to its cost analysis and outcome effect. A review that compared dexmedetomidine to propofol or midazolam for moderate ICU sedation in adults[282] evaluated six cost analyses and two outcome papers. There appeared in most of them to be a small financial benefit to using dexmedetomidine compared to both propofol and midazolam, due to a reduced ICU length of stay. The outcome comparison difference was less noticeable, with a small benefit when comparing dexmedetomidine to midazolam only, due to a lower incidence of delirium, highlighting how difficult this type of comparison may be. These papers focused on adult subjects, whose sedation requirements and complications are different from children, and as such these benefits may not be apparent for a pediatric ICU practice.

CHAPTER 135

Tolerance, Withdrawal, and Dependency

Joseph D. Tobias

PEARLS

- Delaying the onset and magnitude of tolerance and physical dependency may be feasible with the use of newer practices such as drug holidays or nurse-controlled sedation regimens.
- Physical dependency and withdrawal have been documented in all agents used for sedation and analgesia in the pediatric intensive care unit, including benzodiazepines, barbiturates, opioids, dexmedetomidine, propofol, and the inhalational anesthetic agents.
- Regardless of the agent administered, withdrawal will occur once the sedative or analgesic medication has been administered by continuous infusion for more than 4 to 5 days.
- When transitioning from intravenous to oral medications and weaning the amount of medication administered, the use of formal scoring systems to identify withdrawal is recommended.
- In the majority of clinical scenarios, once physical dependency has occurred, withdrawal can be prevented by switching to an orally equivalent agent of the same class such as methadone for the opioids, lorazepam for the benzodiazepines, and clonidine for dexmedetomidine.
- To facilitate care and avoid variations in practice, it is suggested that each institution develop specific protocols for the oral agent to be used, the conversion from intravenous to oral doses, and the tapering regimen.

Introduction

Data demonstrating the potential deleterious physiologic effects of untreated pain combined with ongoing humanitarian concerns have led to increased attention on the need to provide compassionate care in pediatric intensive care unit (PICU) settings. Many of these initiatives have led to increased use of sedative and analgesic agents during mechanical ventilation in infants and children. Although the judicious

use of sedative and analgesic agents is mandatory to ensure effective anxiolysis and analgesia, new consequences have emerged from such practices—including physical dependency, tolerance, and withdrawal—that require definition and effective treatment strategies to limit their impact on the patient, length of hospitalization, and perhaps even outcome.

The development of an effective approach to identifying, preventing, and treating tolerance and physical dependency should begin with a consensus on the definitions of these terms.[1] Tolerance is a decrease in a drug's effect over time, generally with the need to increase the dose to achieve the same effect. Tolerance is related to changes at or distal to the receptor, generally at the cellular level. Some authorities have divided tolerance into various subcategories:

- Innate tolerance refers to a genetically predetermined lack of sensitivity to a drug related to a lack of or alteration in receptors or their subcellular components.
- Pharmacokinetic (dispositional tolerance) refers to changes in a drug's effect because of alterations in distribution or metabolism.
- Learned tolerance refers to a reduction in a drug's effect as a result of learned or compensatory mechanisms (learning to walk a straight line while intoxicated by repeated practice at the task).
- Pharmacodynamic tolerance occurs when drug effect is diminished, although the plasma concentration of the drug remains constant.

For the purpose of this discussion, the latter phenomenon is generally the most relevant to the PICU population and for the remainder of this chapter will be referred to as tolerance.

Withdrawal includes the physical signs and symptoms that manifest when the administration of a medication (for our purposes, the sedative or analgesic agent) is abruptly discontinued in a patient who is physically tolerant. The symptomatology of withdrawal varies from patient to patient and may be affected by several factors including the agent involved as well as the patient's age, cognitive state, and associated medical conditions.

Physiologic (physical) dependence is the need to continue a sedative or analgesic agent to prevent withdrawal. Psychologic dependence is the need for a substance because of its euphoric effects. Addiction is a complex pattern of behaviors characterized by the repetitive, compulsive use of a substance, antisocial or criminal behavior to obtain the drug, and a high incidence of relapse after treatment. Psychologic dependency and addiction are extremely rare after the appropriate use of sedative or analgesic agents to treat pain or to relieve anxiety in the PICU setting.

History of Tolerance and Withdrawal in the Intensive Care Unit Setting

The problems of opioid dependency and withdrawal in neonates and infants were first recognized and studied in the 1970s and 1980s in a population of infants born to mothers with a history of drug addiction.[2,3] Despite the difference in the origin of the problem, these studies provide valuable information for dealing with these issues in the PICU population. They suggested various pharmacologic treatment regimens and provided the first scoring systems used to grade the severity of withdrawal and

to evaluate the efficacy of the treatment regimens.

When considering the PICU population, Arnold and colleagues were among the first to recognize the problems of dependency and withdrawal following prolonged opioid administration.[4] In a retrospective review of 37 neonates who required extracorporeal membrane oxygenation (ECMO) for respiratory failure and who had received intravenous fentanyl for sedation, they sought to identify the signs and symptoms of what they termed "the neonatal abstinence syndrome (NAS)." They also sought to identify risk factors for its occurrence. Fentanyl infusion requirements to achieve the desired level of sedation increased from 11.6 ± 6.9 μg/kg/hr on day 1 to 52.5 ± 19.4 μg/kg/hr on day 8. By measuring plasma fentanyl concentrations, they were able to demonstrate that there was an increase in the plasma fentanyl concentration required to achieve the same level of sedation, thereby demonstrating that the tolerance was pharmacodynamic and not pharmacokinetic (related to increased metabolism of the opioid). The investigators reported that NAS was related to the total fentanyl dose and the duration of the infusion. A cumulative fentanyl dose ≥1.6 mg/kg or an ECMO duration ≥5 days was a risk factor for the development of NAS (odds ratio of 7 and 13.9, respectively). The same investigators subsequently prospectively evaluated fentanyl dosing requirements and plasma fentanyl concentrations in a cohort of eight infants placed on ECMO.[5] Fentanyl infusion requirements increased from 9.2 ± 1.9 μg/kg/hr on day 1 to 21.9 ± 4.5 μg/kg/hr on day 6. As in their previous study, they also noted an increase in the plasma fentanyl concentration from 3.1 ± 1.1 ng/mL on day 1 to 13.9 ± 3.2 ng/mL on day 6. These reports were followed in 1990 by the first report of the use of oral methadone for treatment of iatrogenic dependency and tolerance in the PICU patient.[6] Although this initial report was anecdotal, involving only three to four infants, it has been followed by numerous other investigators outlining the use of methadone in this clinical scenario (discussed later).

Although initially noted with the opioids, subsequent reports demonstrated withdrawal from other agents used for prolonged sedation in the PICU patient including benzodiazepines, barbiturates, propofol, the inhalational anesthetic agents, and most recently dexmedetomidine.[7-9] Additional information concerning benzodiazepine withdrawal is provided by a retrospective review of Fonsmark and colleagues who evaluated 40 patients receiving sedation during mechanical ventilation.[10] Sedation was provided by midazolam, pentobarbital, or a combination of the two. Withdrawal symptoms occurred in 14 of 40 patients (35%). Of the patients with withdrawal symptoms, 8 had received both midazolam and pentobarbital, 3 received only midazolam, and 3 received only pentobarbital. A cumulative midazolam dose ≥60 mg/kg or a cumulative pentobarbital dose ≥25 mg/kg was associated with withdrawal, whereas the duration of the infusion was not. Sedation was gradually tapered in only one of 14 patients who experienced withdrawal. Other anecdotal reports have noted withdrawal following the use of pentobarbital for sedation in the PICU population.[11,12] The potential for the development of tolerance to barbiturates is supported by animal studies.[13,14] Anecdotal and retrospective reports have demonstrated similar withdrawal phenomena following the prolonged administration of propofol and volatile anesthetic agents.[15-18]

Clinical Signs and Symptoms of Withdrawal

The development of strategies to provide effective treatment of physical dependency and related problems requires the accurate identification and recognition of withdrawal symptoms. Ongoing or associated conditions that can manifest clinical signs and symptoms similar to withdrawal must be investigated and ruled out before concluding that the patient's symptoms are the result of withdrawal. In the PICU patient, these associated conditions may include central nervous system insults or infections, ICU psychosis, delirium, metabolic abnormalities, hypoxia, hypercarbia, and cerebral hypoperfusion from alterations in cardiac output or cerebral vascular disease. There has been considerable recognition of the potential confusion of the clinical signs and symptoms of withdrawal with those of delirium.[19,20] Future work in the arena of delirium in the pediatric population as well as improved scoring systems for delirium and withdrawal is needed to differentiate these two problematic disorders.

Although many of the signs and symptoms of withdrawal are the same regardless of the agent, there may be subtle differences depending on the specific medication. The time to the onset of withdrawal symptoms varies depending on the half-life of the agent as well as the half-life of any active metabolites. The latter may be several times longer than the parent compound. In general, the signs and symptoms of withdrawal from sedative and analgesic agents can be localized to one of three end-organ systems: the central nervous system (CNS), the gastrointestinal (GI) tract, and the sympathetic nervous system. CNS manifestations include those of increased activity with irritability including decreased sleep time, tremulousness, hyperactive deep tendon reflexes, clonus, an inability to concentrate, frequent yawning, sneezing, and hypertonicity. As outlined earlier, behaviors now classified as delirium may be a manifestation of withdrawal. In neonates and infants, additional signs of CNS overactivity and stimulation include a high-pitched cry and an exaggerated Moro reflex. Seizures have been reported with withdrawal from various agents including the opioids, benzodiazepines, barbiturates, propofol, and the inhalational anesthetic agents. Visual and auditory hallucinations have been described with opioid, benzodiazepine, barbiturate, and inhalational anesthetic agent withdrawal. GI manifestations include emesis, diarrhea, and feeding intolerance, which may be especially prominent in neonates and infants. When such problems occur in the absence of other signs and symptoms of withdrawal, they may be attributed to other problems and not withdrawal. Activation of the sympathetic nervous system with tachycardia, hypertension, dilated pupils, diaphoresis, and tachypnea is a prominent finding with withdrawal from any of the above-mentioned sedative/analgesic agents. Additional signs and symptoms of sympathetic hyperactivity include nasal stuffiness, sweating, and fever. Although the signs and symptoms of withdrawal may be fairly easy to recognize, it must also be noted that many of these signs and symptoms overlap with potentially life-threatening disorders such as infections, respiratory insufficiency, gastrointestinal ischemia, and cerebral hypoperfusion. As such, the diagnosis of physical dependency and withdrawal must always be a diagnosis of exclusion to avoid potentially missing a life-threatening disorder.

Treatment of Withdrawal and Clinical Scoring Systems

As with most problems that arise in clinical medicine, effective treatment starts with prevention. Given that the incidence of withdrawal is related to the total amount of medication administered, careful titration of the sedative or analgesic agents using clinical sedation scales is suggested. By doing this, it may be practical to use the minimal amount of medication required. One of the more popular tools that has been studied as a means to reduce iatrogenic withdrawal following sedation in the PICU has been the use of nurse-driven protocols.[21,22] Such protocols allow the bedside nurse to adjust the infusion rates of sedative and analgesic as needed to achieve the desired level of sedation. Although limited success has been noted when attempting to demonstrate a decreased length of mechanical ventilation or ICU stay, the initial results are promising in regard to the incidence of withdrawal and physical dependency. In a before-and-after protocol involving 337 medical PICU patients requiring sedation during mechanical ventilation, there was a decrease in the incidence of withdrawal from 23.6% to 12.8% following the initiation of a nurse-driven sedation protocol.[22] The protocol used two different scoring systems including the COMFORT-B and the Nurse Interpretation of Sedation Scores (NISS) as well as the bispectral index (BIS) to assess and adjust the depth of sedation. Based on the protocol, the dosing of sedatives and analgesics (morphine or fentanyl ± midazolam) was adjusted.

Another commonly used technique to encourage the reassessment of the depth of sedation on a daily basis in the adult population is the use of a daily *drug holiday*. This practice involves turning off sedative and analgesic agents until the patient responds and then restarting the infusion at a fraction of the previous infusion rate. Such practices are becoming commonplace in the adult population, as ongoing measures are being evaluated in an attempt to limit the incidence of delirium.[23] Although this is an growing practice in the adult population, there are currently limited data to support or refute the efficacy of so-called drug holidays during the use of sedative and analgesic agents in the PICU setting. The theoretic rationale behind such practices remains sound and would seem to parallel those of using clinical sedation scores in that excessive infusion rates are avoided. With a drug holiday, if the patient is excessively sedated, the amount of medication administered is decreased to the appropriate level. However, physicians and bedside nurses may be hesitant to discontinue effective sedation and analgesia at a time when painful processes may be present in the critically ill patient. Additionally, despite evidence to the contrary in the literature and from current clinical practice, concerns have been raised that this practice may result in periods of excessive agitation in critically ill patients. Robust prospective trials in the pediatric population are needed to demonstrate not only the efficacy but also the safety of such practices.

Other considerations, which also need further investigation, include rotating sedation regimens, intermittent versus continuous infusions of sedative/analgesic agents, and the role of other pharmacologic agents such as *N*-methyl-D-aspartate (NMDA) receptor antagonists (ketamine, methadone, magnesium) or opioid antagonists (naloxone) in preventing tolerance and dependency. Until further investigations provide additional insight into the factors controlling opioid

dependency and ways of preventing or delaying it, PICU physicians will be faced with some patients who require specific actions to prevent the development of withdrawal symptoms. Treatment strategies and protocols are necessary so that the problems associated with tolerance, physical dependency, and withdrawal do not limit the administration of these agents in the PICU population.

Until then, it may be helpful to identify patients who are most likely to manifest symptoms of withdrawal and also to have scoring systems to identify and quantitate the signs and symptoms of withdrawal. As noted previously, risk factors that have been identified include not only the total dose of the sedative or analgesic agent but also the duration of the infusion. In a prospective trial of 23 infants and children who had received fentanyl infusions for sedation during mechanical ventilation, Katz and associates determined the factors that could be used to identify the group at risk of withdrawal.[24] Once sedation was no longer required, the fentanyl infusion was decreased by 50% every 24 hours times two and then discontinued. Withdrawal behavior was observed in 13 of 23 patients (57%). The total fentanyl dose and the duration of the infusion correlated with the risk of withdrawal, whereas the maximum fentanyl infusion rate did not. A total fentanyl dose ≥1.5 mg/kg or an infusion duration ≥5 days was associated with a 50% incidence of withdrawal, whereas a total fentanyl dose ≥2.5 mg/kg or an infusion duration ≥9 days was associated with a 100% incidence of withdrawal.

Scoring systems are essential in the management of patients presenting with signs and symptoms of withdrawal, not only for identifying the behaviors of withdrawal but also for grading its severity and judging the response to therapy. The scoring systems initially used to grade withdrawal were adapted from those developed to deal with neonates born to drug-addicted mothers.[25] As such, these systems were difficult to apply, especially in patients outside of infancy. To address these issues, in 2007 Ista and colleagues reviewed the literature regarding withdrawal scoring systems and found that of the six available in the literature, only two were directed toward the PICU population.[26] The first of was the Sedation Withdrawal Score (SWS), which assigns 0 to 2 points to 12 withdrawal behaviors, thereby providing a maximum score of 24. The signs and symptoms are grouped to the CNS (tremor, irritability, hypertonicity, high-pitched cry, convulsions, and hyperactivity), the GI system (vomiting and diarrhea), and the autonomic nervous system (fever, sweating, sneezing, and respiratory rate).[27] The decision regarding weaning of the current sedative or analgesic medications was based on the score (0–6, wean; 6 to 12, no change; 12 to 18, revert to previous regimen; more than 18, reevaluate plan). Ista and colleagues expressed concerns that the SWS had not been validated in children and that, in particular, there were no data regarding its sensitivity, specificity, validity, and reliability. The other scale reviewed by Ista and colleagues was the Opioid and Benzodiazepine Withdrawal Scale (OBWS) developed by Franck and coworkers.[28] The OBWS is a 21-item checklist evaluating 16 specific withdrawal behaviors. Franck and coworkers evaluated their scale by performing 693 assessments in 15 children, ranging in age from 6 weeks to 28 months. Using 8 as a cut-off score for the absence or presence of withdrawal, the sensitivity of the OBWS was only 50% with a specificity of 87%. The predictive value in terms of positive and negative ratios was 4 and 0.57 (considered moderate for a diagnostic tool), whereas the interrater reliability was acceptable at 0.8.

Based on these issues, Ista and colleagues concluded that a more appropriate scale

was necessary in the PICU population and went on to use the data from their review to develop their own withdrawal scale.[29] From their review of the literature and clinical experience, they developed the Sophia Benzodiazepine and Opioid Withdrawal Checklist (SBOWC), which included 24 withdrawal signs and symptoms. Over a 6-month period, they collected 2188 observations in 79 children within 24 hours of tapering off and discontinuing sedative or analgesic medication. They noted that specific symptoms (including agitation, anxiety, muscle tension, sleeping for less than 1 hour, diarrhea, fever, sweating, and tachypnea) were observed most frequently and that longer duration of opioid or benzodiazepine use and high doses were risk factors for withdrawal. Twenty-three observations were scored simultaneously and resulted in an interobserver correlation coefficient of 0.85 with a range of 0.59 to 1 for the individual items. Subsequent work by Francke and colleagues resulted in the development of the WAT-1 (withdrawal and assessment tool).[30-32] The components of this score are outlined elsewhere.[32] The score is simple and easy to use. It assigns a value of 0 for no or 1 for yes to the following factors: loose or watery stools; vomiting, retching, or gagging; and temperature ≥37.8°C. The patient is then observed for 2 minutes to assess his or her state (asleep, awake, or calm versus distressed), the presence of a tremor, sweating, uncoordinated or repetitive motion, and yawning or sneezing. Again, these factors are scored as 0 for no and 1 for yes. The patient is then observed following a stimulus and during recovery for startle to touch and muscle as well as time to regain a calm state. These components result in a score from 0 to 12.

A high index of suspicion and increasing use of withdrawal scores developed for the PICU patient have advanced our goal of recognizing patients who manifest withdrawal symptoms. As mentioned previously, the mainstay of preventing withdrawal must be the identification of high-risk patients and the slow weaning of sedative and analgesic agents. Withdrawal scales should still be applied to these patients in the event that withdrawal occurs despite our attempts to prevent it. Regardless of the agent administered, it is the cumulative total dose and the duration of infusion that have greatest impact on the incidence of withdrawal. In general, limited or no withdrawal is noted with infusions for ≤3 days, whereas the majority of patients will have withdrawal if the medication is abruptly stopped after 5 days or more. The intermediate zone remains the 3- to 5-day range.

The other issue concerns the optimal method and rate of weaning. Should the medication be weaned incrementally every day using the intravenous route, or should we change to oral medications and wean in that manner? The rate at which the medication is weaned becomes a significant issue when the intravenous route is chosen. If the medication can be weaned by 20% every day, the infusion can be discontinued in 5 days. A more gradual weaning process would mandate prolonged intravenous access unless a transition is made to oral medications. Although it has been suggested that weaning by 10% to 20% is feasible, these studies demonstrate a relatively high incidence of withdrawal, suggesting that a more reasonable approach may be a 5% to 10% decrease per day as has been suggested for adult patients and supported by some in the PICU population.[33-35] It is possible that in some patients, a more rapid wean can be accomplished if the agents have been administered for fewer than 3 to 5 days.

After prolonged administration of 5 or more days, the weaning process will likely require a more protracted period of time to prevent withdrawal symptoms.

Although the weaning process can be accomplished by slowly decreasing the intravenous infusion rate, this mandates the maintenance of intravenous access, ongoing hospitalization, and, at times, continued monitoring in the PICU because, depending on hospital policies, certain medications such as fentanyl or midazolam cannot be administered by continuous infusion in settings other than the PICU. In these circumstances, options to consider include either switching to the subcutaneous route or, most commonly, the use of oral administration.

If it is decided that the infusion can be tapered within a period of time that will not delay hospital discharge and that switching to oral medications will not expedite discharge home, the patient may be considered a candidate for subcutaneous administration (discussed earlier).[36] These patients are generally receiving moderate doses of fentanyl (5–10 μg/kg/hr) or midazolam (0.1–0.3 mg/kg/hr). The switch to the subcutaneous route allows the removal of central venous access, eliminates the need to maintain peripheral intravenous access, and, depending on individual hospital policies, may eliminate the need for ongoing care in the ICU setting. Both fentanyl and midazolam can be effectively administered via the subcutaneous route and the infusions slowly tapered to prevent symptoms of withdrawal. Concentrated solutions of fentanyl (25–50 μg/mL) and midazolam (2.5–5 mg/mL) are used so that the maximum subcutaneous infusion rate does not exceed 3 mL/hr. The subcutaneous infusions are started at the same dose that is currently being used for intravenous administration. A topical dermal anesthetic cream can be placed over the site of anticipated subcutaneous cannulation. Several areas are suitable for subcutaneous administration, including the subclavicular region, abdomen, deltoid, or anterior aspect of the thigh. The site is cleaned, prepped with sterile antiseptic solution, and then either a standard 22-gauge intravenous cannula or a 23-gauge butterfly needle is inserted into the subcutaneous tissue. Before placement, the tubing and needle are flushed with the opioid/benzodiazepine solution. The insertion site is then covered with a transparent, bio-occlusive dressing. The site should be changed every 7 days or sooner if erythema develops. The same infusion pumps that are used for intravenous administration can be used for subcutaneous administration. The pressure limit may need to be adjusted to allow for subcutaneous administration. Alternatively, a syringe pump can be used. If symptoms of withdrawal develop, additional boluses can be administered subcutaneously if necessary. Several opioids can be administered subcutaneously including the synthetic opioids, morphine, hydromorphone, and meperidine. Longer-acting agents such as methadone and levorphanol are not recommended because dose titration may be difficult given the long half-lives of these agents. Tissue reaction and erythema have been noted with methadone. Although there is limited experience with the use of subcutaneous infusions of opioids/benzodiazepines as a means of weaning patients and preventing withdrawal, the subcutaneous route has been used to treat chronic cancer-related pain as well as postoperative pain.[37-40]

When prolonged administration of opioids or other sedative agents will be necessary, switching to the oral administration of long-acting agents such as methadone may allow for earlier hospital discharge. This is especially true in patients who have received weeks of therapy and are on large doses of opioids or benzodiazepines. Advantages of methadone include its longer half-life allowing for dosing two to three times per day, an oral bioavailability of 75% to 90%, and

availability as a liquid. Although the first report regarding the use of methadone suggested a starting dose of 0.1 mg/kg every 12 hours (similar to the analgesic doses that were commonly used), the three patients in the series were receiving relatively low opioid doses and therefore higher doses of methadone were not needed.[6,35] The subsequent clinical experience has indicated that higher doses of methadone will be needed, depending on the dose and duration of opioid that have been administered. When considering the appropriate dose transition from intravenous fentanyl to oral methadone, thought should be given to the differences in the potency and half-life of the two medications as well as crossover tolerance.[35] Similar considerations are necessary when switching from intravenous midazolam to oral lorazepam or from intravenous dexmedetomidine to oral clonidine. Lugo and associates, in a study evaluating enteral lorazepam to decrease midazolam requirements during mechanical ventilation, suggested starting at a lorazepam dose that was one-sixth that of the total daily dose of intravenous midazolam.[41] Once the appropriate enteral/oral dose is determined and therapy started, the intravenous administration is tapered off quickly, generally over a 48-hour period.

After the initial reports regarding the use of methadone, several other authors have suggested variations in conversion ratios from fentanyl to methadone, the use of intravenous and then oral methadone, maintenance dosing intervals, and, most important, weaning schedules.[42-46] In clinical practice, it is useful not to dwell on the individual studies but rather to ensure that each institution has a formal policy for the initial dosing and subsequent weaning of methadone. This practice is suggested to avoid the natural variations that occur in physician practice, which may impact the success of such programs.[47] Regardless of the protocol used, close observation during the conversion period is necessary to avoid adverse effects from oversedation or to recognize the early symptoms of withdrawal. This observation should use some formal scoring system to evaluate infants for and score the magnitude of withdrawal when it occurs.

Given the advantages outlined here, methadone is now the common choice for the opioid-dependent infant in the PICU. However, some stigmata remain concerning the use of methadone. A thorough discussion with the parents is necessary to discuss why methadone is being used and to outline the differences between addiction and physical dependency. Because of these issues as well as familiarity with long-acting morphine preparations, which are used in the treatment of children with chronic cancer-related pain, some physicians have used long-acting preparations of morphine. However, these agents are available only in tablets that cannot be crushed so that administration and subsequent weaning protocols may be more difficult in younger patients. Methadone on the other hand is available in a liquid formulation. Concern has been expressed regarding adults who are on maintenance methadone for drug addiction in terms of the potential for death from QT prolongation and arrhythmias.[48] To date, there are no reports from the pediatric population; however, these concerns have led to the consideration of obtaining periodic ECGs prior to and after instituting therapy with methadone. Given the multitude of medications used in the PICU patient, avoidance of interactions with other agents that can potentially prolong the QT interval is suggested. A final issue with methadone is its metabolism by the P-450 isoenzyme system of the liver, making alterations in metabolism possible based on genetic factors and the co-administration of other medications. These factors should be considered when

methadone is started or other medications are added to the patient's regimen.

In addition to opioids, nonopioid agents have been used to treat opioid withdrawal. This practice was relatively common when treating the withdrawal of infants born to drug-addicted mothers. In many cases, paregoric or other crude opioid preparations were used or, alternatively, barbiturates such as phenobarbital were given to control the clinical signs and symptoms. This would appear less than optimal, as it seems to make physiologic sense when dealing with the problems of tolerance and physical dependency to replace the missing agent rather than to treat the resulting symptoms. Given these concerns, our current clinical practice is generally to use a medication in the same class as the one resulting in withdrawal. However, in specific clinical scenarios, the centrally acting α_2-adrenergic agonists, clonidine and dexmedetomidine, have been used to treat and prevent opioid and benzodiazepine withdrawal.[49-52]

With the significant increase in the use of dexmedetomidine in the PICU in various clinical scenarios, withdrawal from this agent is becoming a more commonly encountered clinical problem. Dexmedetomidine (Precedex, Hospira Worldwide Inc, Lake Forest, Illinois) exerts its physiologic effects via α_2-adrenergic receptors, thereby making it a novel pharmacologic agent for sedation in various clinical scenarios. Given its beneficial physiologic effects and favorable adverse effect profile, it has made its way into the pediatric pharmacologic armamentarium in various clinical scenarios including sedation during mechanical ventilation, procedural sedation, the treatment of withdrawal, and the prevention of emergence agitation. It was speculated that this novel agent might cause little or no tolerance with prolonged infusion and that the infusion might be abruptly discontinued even following prolonged administration.[53,54] Walker and colleagues reported retrospective data regarding dexmedetomidine infusions in 65 pediatric patients (mean age of 5 years) with thermal injuries.[55] The duration of the infusion varied from 2 to 50 days (mean duration of 11 days). They noted no tachyphylaxis and no evidence of withdrawal or rebound hemodynamic effects when the infusions were weaned and discontinued over a 12- to 24-hour period. However, with increased use and clinical experience came the reports of tolerance, physical dependency, and withdrawal. Enomoto and associates used dexmedetomidine for 2 months to sedate an infant with respiratory failure following hepatic transplantation.[56] Tolerance was manifested by the need to increase the infusion from a starting dose of 0.4 μg/kg/hr to a maximum of 1.4 μg/kg/hr to achieve the desired level of sedation. At one point when the infusion was weaned over 48 hours to exclude drug-induced hepatic dysfunction, the child became anxious, developed hypertension, and his respiratory status deteriorated within 6 hours of stopping the infusion. These problems resolved upon restarting the dexmedetomidine infusion. Weber and coworkers reported hypertension, tachycardia, and emesis in a 2-year-old child when dexmedetomidine was discontinued after 6 days of administration.[57] The symptoms were effectively controlled by restarting the infusion and then incrementally decreasing the infusion by 0.1 μg/kg/hr every 8 hours. Similar anecdotal experiences demonstrating withdrawal symptoms from dexmedetomidine were reported by Darnell and colleagues.[58]

More compelling evidence for withdrawal from dexmedetomidine was provided by Honey and associates in their evaluation of adverse effects related to dexmedetomidine infusions used for sedation in the PICU setting.[59] Over a 12-month

period, data were collected on 36 children who received continuous infusions of dexmedetomidine. Although the median duration of the infusion was 20 hours, the range varied from 3 to 263 hours. Neurologic issues were noted in 4 patients following dexmedetomidine infusions. One patient who received dexmedetomidine for 11 days developed decreased verbal communication, facial drooping, and unilateral papillary dilatation when the infusion was discontinued without tapering. Transient neurologic events, including increased agitation, abnormal chewing movements, nonreactive pupils, slow rhythmic jerking movements, and abnormal head turning, were noted in 3 other patients who had received dexmedetomidine for 6 to 49 hours. The infusion was tapered in 2 of these patients. Of additional note, these authors suggested that adverse events related to dexmedetomidine were more likely when the cumulative dose was ≥8.5 μg/kg.

Potential options to prevent such occurrences are to not abruptly discontinue the infusion following prolonged infusions of more than 4 to 5 days. Options to allow for its discontinuation include a slow taper via the intravenous route (0.1 μg/kg/hr every 12–24 hours), switching to an orally equivalent dose of clonidine, use of transdermal clonidine, and changing to subcutaneous administration (which can be used to eliminate the need for ongoing intravenous access).[52] In common clinical practice, most centers have adopted a regimen that involves the transition from intravenous dexmedetomidine to oral clonidine followed by a gradual taper of the oral clonidine dose. Two reports provide useful information regarding this practice.[60,61] In the first, the intent was to transition from intravenous dexmedetomidine to oral clonidine to decrease the cost of the ongoing intravenous dexmedetomidine infusion.[60] The study cohort included 20 adult patients for whom an attempt was made to transition over a 48-hour period from intravenous dexmedetomidine to enteral clonidine (0.3 mg every 6 hours). The transition was successful in 75% of the cohort with only one patient demonstrating symptoms of withdrawal. The authors also noted a decrease in fentanyl requirements in patients receiving oral clonidine compared to intravenous fentanyl (387 versus 891 μg/day) as well as a significant reduction in drug acquisition costs.

A subsequent study involved a retrospective review to assess the efficacy of a transition from intravenous dexmedetomidine to transdermal clonidine as a means of preventing withdrawal.[61] Withdrawal Assessment Tool-1 (WAT-1) scores and hemodynamic parameters were collected from pediatric patients who received intravenous dexmedetomidine for ≥5 days. The study cohort included 19 pediatric patients, 12 of whom received clonidine. For the 24 hours after weaning and transition to clonidine, there was a trend for a decreased number of elevated WAT-1 scores in patients receiving clonidine versus the no clonidine group (mean of 0.8 versus 3.2). Another option is the transition to oral clonidine. Despite limited evidence-based medicine for this practice, clinical experience has suggested that the transition from intravenous dexmedetomidine to oral clonidine can be accomplished over a 48-hour period with a clonidine dose of 3 to 5 μg/kg/dose every 6 to 8 hours.

Summary

With attention to the need for more aggressive sedation and analgesia during prolonged critical illness, the newer issues of physical tolerance and withdrawal have become more pervasive. Although preventing or at least delaying tolerance

may be feasible using newer practices such as drug holidays or nurse-controlled sedation regimens, treatment algorithms are needed to avoid the adverse physiologic effects of these problems and to limit their impact on length of hospitalization. Clinical studies show consistently that regardless of the agent administered, withdrawal will occur once the sedative or analgesic medication has been administered by continuous infusion for more than 4 to 5 days. In those scenarios, the most commonly employed option is switching to an orally equivalent agent. During this process and as the oral agent is weaned, ongoing monitoring with a withdrawal score is suggested. To facilitate care and avoid variations in practice, many institutions have developed specific protocols for the oral agent to be used, the conversion from intravenous to oral doses, and the tapering regimen. By aggressively managing the issues of tolerance, physical dependency, and withdrawal, their impact on the effective provision of sedation and analgesia during critical illness can be minimized.

CHAPTER 136

Pediatric Delirium

Chani Traube, Bruce M. Greenwald

PEARLS

- Delirium is a potentially prevalent and serious sequela of pediatric critical illness.
- Refractory agitation in the pediatric intensive care unit is often a manifestation of delirium.
- Hypoactive delirium is frequently missed.
- Unit-wide screening for delirium is feasible with valid and reliable bedside tools.
- Detecting and treating pediatric delirium may improve short- and long-term outcomes.

Introduction

Delirium is the behavioral manifestation of acute global brain dysfunction. It is defined by the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-V), as a disturbance of awareness and cognition, and it is characterized by an acute onset and a fluctuating course. Importantly, delirium is not a psychiatric diagnosis but is rather a complication of an underlying general medical condition.[1]

There are three principal subtypes of delirium. Hyperactive delirium (previously referred to in the intensive care unit [ICU] community as *ICU psychosis*) is characterized by agitation, restlessness, and emotional lability. Hypoactive delirium (sometimes called *encephalopathy of critical illness*) is notable for apathy and decreased responsiveness. Mixed delirium represents fluctuation between symptoms of both hyperactive and hypoactive delirium. Hyperactive delirium is the subtype most readily recognized. Conversely, unless there is a high index of suspicion, hypoactive delirium is often missed.[2-5]

Background

In January 2013, the Society of Critical Care Medicine (SCCM) published “Clinical Practice Guidelines for the Management of Pain, Agitation, and Delirium in Adult Patients in the Intensive Care Unit.” The SCCM guidelines recommend routine

monitoring for delirium in adult ICU patients, as "monitoring critically ill patients for delirium with valid and reliable delirium assessment tools enables clinicians to potentially detect and treat delirium sooner, and possibly improve outcomes."[6] This was the result of an explosion of delirium research, with thousands of articles published in peer-reviewed journals.[6]

Delirium is endemic in adult ICUs. With an overall prevalence of greater than 30%, it is more common in the elderly and affects up to 80% of adults on mechanical ventilation. Delirium in adults has been linked to increased mortality, increased ICU length of stay, increased hospital length of stay, long-term cognitive impairment, and postintensive care syndrome. Median time to tracheal extubation is longer in delirious patients, and delirium has been associated with various ICU morbidities such as self-extubation and removal of catheters.[6-12] The association with mortality is strong, with duration of delirium correlated with increased risk. Two well-designed cohort studies in adult ICUs reported that for each day spent delirious, there was an increase in mortality.[11,13] In addition, delirium has been associated with significantly increased health care costs.[6,14]

Delirium in critically ill children has only recently received attention in the pediatric critical care literature. As in adults, it has been associated with severity of illness, prolongation of time to tracheal extubation, and increased hospital length of stay.[15-17] There is a robust relationship between pediatric delirium and increased hospital costs.[16,18] Delirium in children has been linked to delusional memories, perceptual-motor and behavior problems, and posttraumatic stress disorder.[19,20] Importantly, ICU medical and nursing practices can affect delirium rates. Therefore accurate and early recognition of delirium in critically ill patients is imperative.[6]

Etiology

The etiology of delirium is complex and the pathophysiology incompletely understood. An interruption of brain network connections occurs, with a failure of the integration and processing of sensory information and motor responses.[21] Much research has demonstrated that regardless of the primary etiology, the final common pathway involves alteration in neurotransmission, with subsequent cognitive and behavioral changes in the affected individual. Neurotransmitter dysregulation includes deficient acetylcholine and melatonin; excess dopamine, glutamate, and norepinephrine; and variable changes in gamma-aminobutyric acid (GABA), serotonin, and histamine.[22,23]

The cholinergic system modulates attention and consciousness, sleep, and memory.[24,25] Animal models have shown decreased acetylcholine synthesis in animals subjected to hypoxia/hypoxemia and immobilization.[22] Anticholinergic agents have long been implicated in the genesis of delirium, with the elderly at increased risk, likely due to an age-related decrease in acetylcholine synthesis in the hippocampus and prefrontal cortex.[13,26,27] Notably, children under 5 years of age have decreased acetylcholine synthesis in these areas as well.

A literature review by Maldonado described a range of etiologic theories as to the processes underlying delirium. These mechanisms are interrelated and likely synergistic in critically ill patients.[22] The neuroinflammatory hypothesis proposes that systemic inflammation from an underlying illness, with associated cytokine release, compromises the integrity of the blood-brain barrier. This results in CNS

inflammation that leads to dysfunction of neurons and synapses.[28] Numerous studies in adults have shown that delirious patients have elevation of proinflammatory cytokines as compared to nondelirious patients, even after adjusting for multiple confounders.[29-31]

The neuronal aging hypothesis proposes that the elderly brain is more vulnerable to experiencing delirium due to a lack of physiologic reserve when the patient is seriously ill. In fact, dementia is the single strongest risk factor for delirium in the elderly.[32,33] In a damaged brain, microglia are primed to respond more vigorously to systemic inflammation.[34] This may be relevant to the population of developmentally delayed children in the pediatric ICU, a group that has been shown to be at higher risk for developing delirium than developmentally typical children.[16]

The oxidative stress hypothesis maintains that delirium represents *cerebral insufficiency*.[35] This is a form of brain failure, due to either hypoxia or hypoperfusion, which generates reactive oxygen species that induce oxidative damage. Several studies have demonstrated a correlation between hypoxia and delirium in both adults and children.[16,36,37]

The neuroendocrine hypothesis suggests that physiologic stress leads to an elaboration of glucocorticoids that cause direct neuronal injury.[22] The diurnal (or melatonin) dysregulation theory posits that disruption of sleep architecture can precipitate, and then perpetuate, delirium.[38,39]

Clinically, delirium can be thought of as the result of three synergistic factors: (1) the underlying illness, (2) the iatrogenic effects of the treatment for that illness, and (3) the highly abnormal ICU environment. As an example, consider the child who has recently undergone surgical repair of a congenital cardiac anomaly utilizing cardiopulmonary bypass. There may have been episodes of hypoxemia and hypotension in the perioperative period, which led to brain hypoperfusion. The postoperative state is characterized by inflammation and mechanical ventilation, both of which are associated with delirium. There has been exposure to anesthetic agents, and the patient is currently receiving opiates and benzodiazepines, which have been strongly linked to delirium. The patient is bedridden in an ICU and may also be immobilized, sleep deprived, and exposed to lights and noises 24 hours a day. These circumstances act together to form the framework for the emergence of delirium in this child.

Epidemiology

The prevalence of delirium in the pediatric ICU has been reported as ranging from approximately 10% to 30%.[40] A study completed in 2010, during the validation of a pediatric delirium screening tool, demonstrated a rate of 12.3%, but this study included only children over 5 years of age, and only 6% were receiving mechanical ventilation.[41] Thus, those children in the ICU most at risk for delirium may have inadvertently been either excluded or underrepresented. A more recent study included children from newborn to 21 years of age, with approximately 25% of patients receiving invasive mechanical ventilation. This study showed a prevalence rate of 21%[42] (Fig. 136.1).

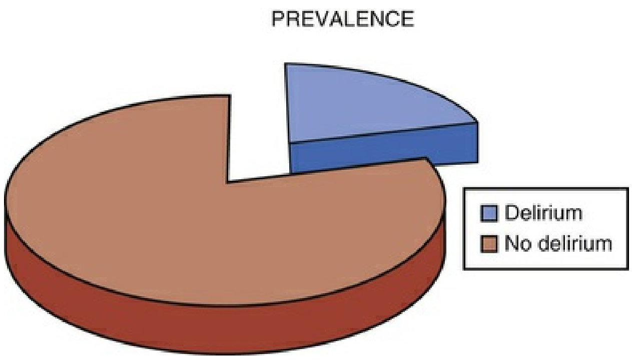

FIG. 136.1 Delirium prevalence in children newborn to 21 years of age. (From Traube C, Silver G, Kearney J, et al. Cornell Assessment of Pediatric Delirium: a valid, rapid, observational tool for screening delirium in the PICU. Crit Care Med. 2014;42:656-6563.)

Risk Factors

Baseline risk factors associated with delirium in adults are dementia, hypertension, alcoholism, male gender, cigarette use, and high severity of illness at admission.[6] Modifiable risk factors include depth of sedation, use of restraints, and choice of sedating medications. Adult ICU delirium has been associated with the use and dose of benzodiazepines, physical restraints, and the use of antipsychotics.[6,43-48] A prospective observational study described risk factors for pediatric delirium. In this single-center study, delirium was associated with increased severity of illness. After controlling for this and other possible confounders, risk factors for the development of delirium included preschool age, preexisting neurodevelopmental delay, escalating need for respiratory support, and concomitant sedation[16] (Fig. 136.2). There was a significantly greater incidence of delirium in children 2 to 5 years of age, with an adjusted odds ratio of 2.6 when compared with younger children and 8.8 when compared with adolescents. This may be a function of sleep deprivation and immobilization, which are conditions that are particularly disruptive to preschool-age children[16] (Table 136.1). Similarly, children with underlying developmental delay were at increased risk, with an adjusted odds ratio of 3.5 when compared with developmentally typical children. This may represent a lack of physiologic reserve in this atypical brain, similar to the increased prevalence of delirium in the geriatric population[16,22] (see Table 136.1). Children receiving invasive mechanical ventilation, who were necessarily exposed to sedatives, also had an increased delirium rate, with an adjusted odds ratio of 3.9. Importantly, this presents a possible modifiable risk factor, as clinicians can adjust their target sedation depth and their choice of sedative agents[16] (see Table 136.1).

Clinical Presentation

Pediatric delirium is complex and multifactorial, and it is further confounded by developmental variability. Normal behavior in a 2-year-old would be considered highly abnormal behavior in a 12-year-old. Thus, the developmental context is integral to the diagnosis of delirium in children. In fact, in early pediatric delirium

research, questions were raised regarding the reliability of the DSM criteria in the diagnosis of delirium in young children, particularly preverbal children. To address this issue, Silver and colleagues investigated the reliability of the criterion standard (delirium diagnosis by psychiatric examination utilizing the DSM-IV criteria) by performing 38 paired psychiatric evaluations of children at risk for delirium by two different psychiatrists. Fifty percent of the children in this cohort were under 2 years of age. Interrater reliability of the paired psychiatric assessments was excellent, with a kappa of 0.95, demonstrating the reliability of the standard criteria for diagnosis of delirium in children.[49]

Delirium in critically ill adults is most often of the hypoactive subtype.[2,3,43] An emerging literature indicates that pediatric delirium is frequently mixed, with transition between hypo- and hyperactive symptoms occurring over the course of a single day. Hyperactive delirium is more readily recognized, as the child is actively interfering with the medical team's interventions. In the past, these children frequently received large doses of sedatives, which further contributed to the evolving delirium. It is this hyperactive subtype of delirium that is generally noted.[50] However, it represents only a portion of all delirium and generally has the best prognosis.[43]

It is the docile child, often termed the “good patient,” who lies in his or her bed without protest and allows the care team to do whatever uncomfortable interventions are necessary, whose condition often goes unnoticed. This is markedly abnormal behavior for a preschool and school-age child and likely represents hypoactive delirium.[51,52] Hypoactive delirium is often missed without routine screening[5] and has been linked to the worst prognosis in multiple studies in adult patients.[53,54] With timely recognition and treatment, the duration of delirium can be decreased.

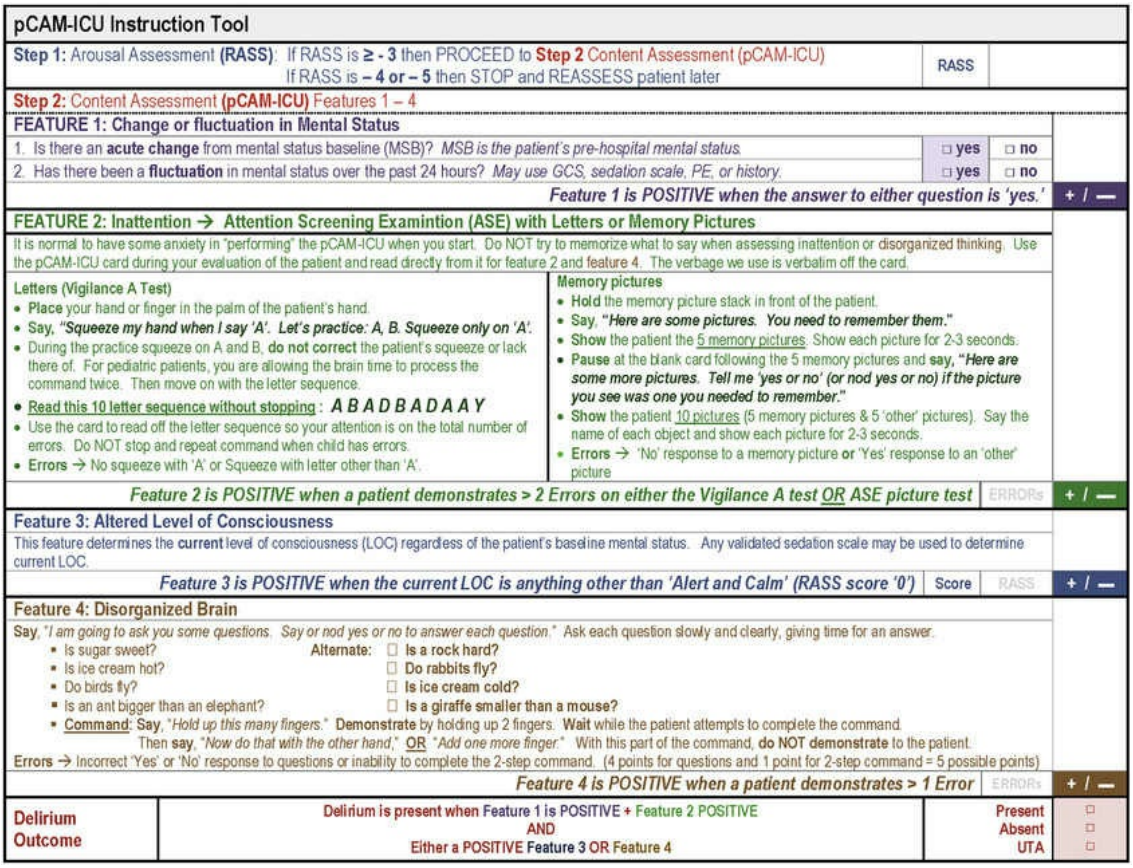
Children with delirium can present with a range of alterations in psychomotor activity, including fidgetiness and self-stimulating behavior or sluggish responses to interactions. Children and adolescents may have a disordered emotional state, with extreme tearfulness, inconsolability, or an inappropriate calmness relative to their circumstances. In addition, pediatric delirium is often marked by profound sleep disturbance, which itself further worsens the delirium.[18,52,55]

The diagnosis of delirium may be challenging in the developmentally delayed child. As such, this at-risk subgroup is often omitted from research. This is unfortunate, and unnecessary, as delirium can be distinguished from static encephalopathy. With attention to the child's prehospital baseline and focus on fluctuation (a hallmark of delirium) in current symptoms, delirium can be reliably diagnosed even in this hard-to-assess population.[49,51]

Diagnosis

Until recently, the only way to diagnose delirium in children was via a psychiatric interview and examination, utilizing the DSM criteria. This is time consuming, expensive, and relies on a limited resource (pediatric psychiatrists). This explains why, historically, only children with hyperactive delirium were recognized and received appropriate attention. The advent of bedside delirium screening tools presents an opportunity to assess all critically ill children for delirium.[56-58] Two validated tools are currently available for use in the pediatric intensive care unit

(PICU). The Pediatric Confusion Assessment Method for the ICU (pCAM-ICU) is a tool derived from the well-validated and widely used CAM-ICU. It uses yes/no questions, hand signals, and pictures and has been designed for use in children >5 years old, without significant developmental delay. It is a point-in-time interactive and cognitively oriented assessment. Delirium is scored as present or absent[41] (Fig. 136.3).



pCAM-ICU Instruction Tool

Step 1: Arousal Assessment **(RASS)**: If RASS is **≥ - 3** then PROCEED to **Step 2** Content Assessment (pCAM-ICU)
If RASS is **– 4 or – 5** then STOP and REASSESS patient later | RASS

Step 2: Content Assessment **(pCAM-ICU)** Features 1 – 4

FEATURE 1: Change or fluctuation in Mental Status

1. Is there an **acute change** from mental status baseline (MSB)? *MSB is the patient's pre-hospital mental status.* ☐ yes ☐ no
2. Has there been a **fluctuation** in mental status over the past 24 hours? *May use GCS, sedation scale, PE, or history.* ☐ yes ☐ no

Feature 1 is POSITIVE when the answer to either question is 'yes.' + / —

FEATURE 2: Inattention → Attention Screening Examintion (ASE) with Letters or Memory Pictures

It is normal to have some anxiety in "performing" the pCAM-ICU when you start. Do NOT try to memorize what to say when assessing inattention or disorganized thinking. Use the pCAM-ICU card during your evaluation of the patient and read directly from it for feature 2 and feature 4. The verbage we use is verbatim off the card.

Letters (Vigilance A Test)

- **Place** your hand or finger in the palm of the patient's hand.
- **Say,** ***"Squeeze my hand when I say 'A'. Let's practice: A, B. Squeeze only on 'A'.***
- During the practice squeeze on A and B, **do not correct** the patient's squeeze or lack there of. For pediatric patients, you are allowing the brain time to process the command twice. Then move on with the letter sequence.
- **Read this 10 letter sequence without stopping**: ***A B A D B A D A A Y***
- Use the card to read off the letter sequence so your attention is on the total number of errors. Do NOT stop and repeat command when child has errors.
- **Errors** → No squeeze with 'A' or Squeeze with letter other than 'A'.

Memory pictures

- **Hold** the memory picture stack in front of the patient.
- **Say**, ***"Here are some pictures. You need to remember them."***
- **Show** the patient the 5 memory pictures. Show each picture for 2-3 seconds.
- **Pause** at the blank card following the 5 memory pictures and **say, *"Here are some more pictures. Tell me 'yes or no' (or nod yes or no) if the picture you see was one you needed to remember."***
- **Show** the patient 10 pictures (5 memory pictures & 5 'other' pictures). Say the name of each object and show each picture for 2-3 seconds.
- **Errors** → 'No' response to a memory picture **or** 'Yes' response to an 'other' picture

Feature 2 is POSITIVE when a patient demonstrates > 2 Errors on either the Vigilance A test OR ASE picture test | ERRORs | + / —

Feature 3: Altered Level of Consciousness

This feature determines the **current** level of consciousness (LOC) regardless of the patient's baseline mental status. Any validated sedation scale may be used to determine current LOC.

Feature 3 is POSITIVE when the current LOC is anything other than 'Alert and Calm' (RASS score '0') | Score | RASS | + / —

Feature 4: Disorganized Brain

Say, *"I am going to ask you some questions. Say or nod yes or no to answer each question."* Ask each question slowly and clearly, giving time for an answer.

- Is sugar sweet? — **Alternate:** ☐ **Is a rock hard?**
- Is ice cream hot? — ☐ **Do rabbits fly?**
- Do birds fly? — ☐ **Is ice cream cold?**
- Is an ant bigger than an elephant? — ☐ **Is a giraffe smaller than a mouse?**
- Command: **Say**, *"Hold up this many fingers."* **Demonstrate** by holding up 2 fingers. **Wait** while the patient attempts to complete the command.
  Then **say**, *"Now do that with the other hand,"* OR *"Add one more finger."* With this part of the command, **do NOT demonstrate** to the patient.

Errors → Incorrect 'Yes' or 'No' response to questions or inability to complete the 2-step command. (4 points for questions and 1 point for 2-step command = 5 possible points)

Feature 4 is POSITIVE when a patient demonstrates > 1 Error | ERRORs | + / —

Delirium Outcome	**Delirium is present when Feature 1 is POSITIVE + Feature 2 POSITIVE** **AND** **Either a POSITIVE Feature 3 OR Feature 4**	**Present** **Absent** **UTA**	☐ ☐ ☐

FIG. 136.3 Pediatric Confusion Assessment Method for the ICU. (Reproduced from http://www.icudelirium.org/docs/Instruction-Tool_pCAM-ICU.pdf.)

The Cornell Assessment of Pediatric Delirium is a strictly observational tool, with eight questions that are scored by the bedside nurse on a Likert scale. The elements of the tool are consistent with the diagnostic criteria for delirium. It is designed to be applicable to children of all ages and cognitive levels.[42] A Developmental Anchor Points chart is available for the nurse to use as a point-of-care reference when administering the tool in the youngest, preverbal patients.[51] The screen is scored on a numeric scale, with a score of 9 or higher consistent with a diagnosis of delirium in a developmentally typical child. The individual's score can be trended over time to determine response to interventions[42] (Fig. 136.4). With real-time bedside screening now available, a growing number of pediatric ICUs in North America and Europe have implemented delirium screening as part of their routine care. Screening takes less than 2 minutes per patient and is essential to ensure early detection (when delirium is most amenable to treatment) of both hyperactive and hypoactive delirium (Fig. 136.5).

RASS score____(if –4 or –5 do not proceed)

Please answer the following questions based on your interactions with the patient over the course of your shift:

	Never 4	Rarely 3	Sometimes 2	Often 1	Always 0	Score
1. Does the child make eye contact with the caregiver?						
2. Are the child's actions purposeful?						
3. Is the child aware of his/her surroundings?						
4. Does the child communicate needs and wants?						
	Never 0	Rarely 1	Sometimes 2	Often 3	Always 4	
5. Is the child restless?						
6. Is the child inconsolable?						
7. Is the child underactive—very little movement while awake?						
8. Does it take the child a long time to respond to interactions?						
					Total	

FIG. 136.4 Cornell Assessment for Pediatric Delirium. (Reproduced from Traube C, Silver G, Kearney J, et al. Cornell Assessment of Pediatric Delirium: a valid, rapid, observational tool for screening delirium in the PICU. Crit Care Med. 2014;42:656-663.)

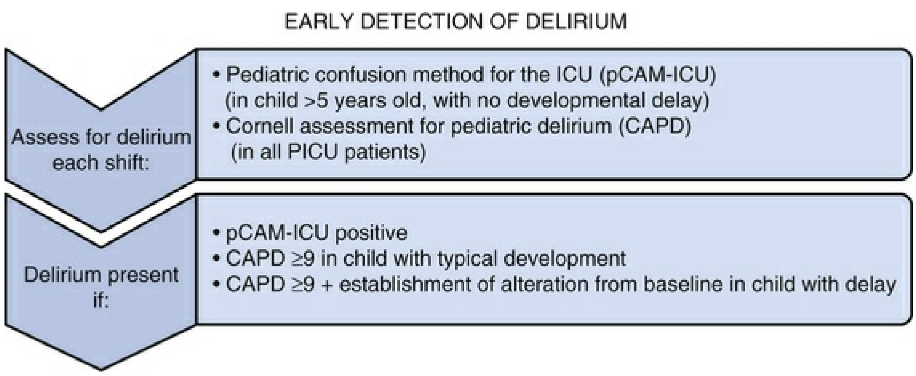


FIG. 136.5 Detection of delirium.

Treatment

With increasing awareness in the pediatric critical care community as to the prevalence and possibly poor prognostic implications of delirium, as well as the ability to identify children with delirium in real time, targeted interventions may be employed to minimize its duration and potentially ameliorate the long-term effects of delirium. Just as delirium is caused by three associated triggers (underlying illness, complications of therapy, and the environment of care), when delirium is

diagnosed, attention should be focused on these three areas as well (Fig. 136.6).

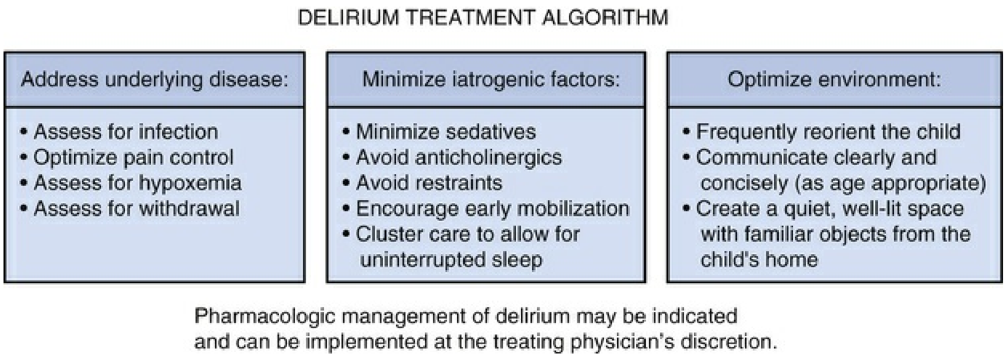

FIG. 136.6 Delirium treatment algorithm.

Underlying Illness

Timely detection of delirium offers an early warning sign—a call to attention that something significant is occurring. A positive delirium screen should lead to a series of clinical questions. Is a new infection brewing? (Delirium symptoms often precede the fever heralding the new infection). Is there evolving respiratory or hepatic or renal insufficiency leading to metabolic abnormalities? Is there a new, primary neurologic problem? A focused evaluation, including physical examination, neurologic examination, and appropriate laboratory workup, is indicated.[59]

Iatrogenic Factors

Following assessment for previously undetected illness, attention should turn to the numerous clinical factors that can lead to delirium. Pain control should be optimized with appropriate use of opiates and nonopiate analgesics.[60,61] Sedation should be minimized, as clinically appropriate. A patient on invasive mechanical ventilation, whose sedative regimen has been steadily escalated over the course of hours to days, may be delirious as a direct result of the sedatives and will often improve with removal of the offending agents.[62] Many experts feel that benzodiazepines are particularly problematic and that escalating dosages result in increased risk for delirium and excess ventilator days.[48] In years past, clinicians hoped to decrease the traumatic effect of hospitalization by sedating the child; recent data indicates that this is counterproductive, interferes with the clinician's ability to adequately recognize and treat pain, and may increase the risk of delusional memories and posttraumatic stress disorder.[19,63] More recently, many pediatric intensivists have adopted the philosophy that it is better for a critically ill patient to be awake and occasionally upset—with reassurance provided by the parents and the clinical care team—than to “sleep” through his or her ICU stay.[16]

Opiate and benzodiazepine withdrawal can precipitate delirium, but it is important to differentiate the physiologic signs of abstinence from the behavioral symptoms of hyperactive delirium. In fact, a child with hyperactive delirium who has never been on an opiate will score positive on a number of withdrawal

assessment tools.[64,65] If delirium is triggered by opiate withdrawal, simply replacing the missing opiate is often insufficient to reverse the symptoms. Judicious replacement of the opiate is necessary, but it is important to then approach the delirium as a primary problem, rather than continue to escalate the opiate dose, as this will simply prolong the delirium exposure.[16]

Reviewing the patient's medication list is essential. Anticholinergic agents and medications with anticholinergic effects may be routinely and often unnecessarily used in the PICU and can frequently be discontinued or replaced.[24] If a child with hyperactive delirium is on corticosteroids, a taper should be considered. The literature indicates that benzodiazepines increase delirium rates in critically ill adults; ongoing research in pediatrics suggests the same. Consideration should be given to minimizing the use of benzodiazepines and replacing these agents with dexmedetomidine when sedation is necessary.[6,47,48,66]

Environment

Optimizing the environment is an achievable goal.[67] It is important to ensure that children who require corrective lenses have their glasses on when awake. Creating a well-lit and uncluttered space during the day is feasible and effective. Educating parents and staff to limit guests and avoid commotion at the bedside is essential. Familiar items from home such as a favorite blanket or stuffed toy are more effective than new gifts. Helium balloons can be disconcerting to a lightly sedated child as they move spontaneously and can contribute to hallucinations.

In adults, early mobilization has been shown to decrease delirium rates and shorten delirium once it occurs.[68-70] Implementation of an early mobilization protocol in the PICU does not have to be as dramatic as walking an intubated child; it can start as a simple change in approach and mindset. A child on invasive mechanical ventilation should be permitted to have periods of wakefulness as well as sleep; deep sedation should be avoided. When awake, passive range-of-motion activities in bed can be performed by the nurse or an appropriately supervised family member. Even young children can be safely maintained with a light level of sedation, awake on the ventilator, and interacting with caregivers.[16,71]

A difficult challenge is establishing a sleep-friendly environment within the PICU.[72] Asking the parents to describe the child's preferred sleep position can be helpful—a toddler who always sleeps in the prone position at home will have enormous difficulty remaining asleep on his back while critically ill, so repositioning may help. Attempts to ensure a quiet, dark environment at night and encouraging parents to continue their usual bedtime routines (such as a storybook or back rub) can help facilitate sleep, even in the ICU.

Pharmacotherapy

In 15% to 20% of cases, attempts to address the underlying illness, minimize therapeutic triggers, and optimize the environment are not enough, and persistent delirium symptoms interfere with necessary medical interventions. In such instances, pharmacologic therapy for delirium may be indicated.[67] Currently no drug has been approved by the Food and Drug Administration to treat delirium in either

adults or children, but the consensus approach is to use antipsychotic agents (either haloperidol or the atypical antipsychotics due to their more favorable side effect profiles).[6] These procognitive drugs regulate neurotransmitters and can help organize thoughts and calm the delirious patient. This may facilitate the patient's cooperation with ongoing medical care and allow the opportunity for the patient to wean from other medications that promote delirium.[73]

Evidence for pharmacotherapy is scarce. One randomized, placebo-controlled study showed a reduction of the duration of delirium with quetiapine (an atypical antipsychotic medication) in critically ill adults.[74] There have been several case series describing the successful use of atypical antipsychotic agents (including olanzapine, quetiapine, and risperidone) to treat delirium in young children, but no prospective efficacy studies have been conducted to date.[71,75-78] A retrospective study designed to evaluate the safety of quetiapine in treating delirium in critically ill children found no serious adverse events with >2400 doses administered.[79] There are no published data showing that treatment with haloperidol reduces the duration of delirium in adults or children, although it remains a reasonable choice and a mainstay of treatment in many ICUs.[73,80] Further research is needed to systematically assess the safety and efficacy of antipsychotics in the treatment of pediatric delirium.

Prevention

Prevention of delirium remains an elusive goal. Data in adults suggest that early mobilization of critically ill patients will reduce the incidence of delirium and shorten its duration.[69,70] In hospitalized adults who are not critically ill, a multicomponent intervention, with protocols for cognition, sleep, mobility, vision, hearing, and hydration, decreased delirium rates.[81] There is no evidence that prophylactic administration of antipsychotics decreases delirium rates in the general ICU population, although a subset of elderly patients, or those after cardiac surgery, may benefit in the immediate postoperative period when their delirium rates are quite high.[80,82-84] There are currently no prospective studies describing effective preventive strategies for the development of delirium in critically ill children. Further research is necessary and under way.

Conclusion

Delirium is prevalent in critical illness and is associated with significant short- and longer-term morbidity. Children are at significant risk of developing delirium while in the pediatric ICU. With increased awareness of this common problem, pediatric intensivists can detect delirium sooner and implement strategies to treat and prevent this serious complication of PICU care. Further research is needed to improve the care provided to this vulnerable population.

Section XIV

OUTLINE

Board Review Questions

Monica Relvas

Chapter 1: History of Pediatric Critical Care Medicine

1. Treatment for which of the following disease entities was not an important trigger in the early development of distinct, full-time, multidisciplinary pediatric intensive care units?
   A. Measles
   B. Poliomyelitis
   C. Reye syndrome
   D. Tetanus
   Preferred response: A

Rationale

In Europe, pediatric intensive care followed shortly after the poliomyelitis epidemic in Denmark in 1952. In 1955, Dr. Goran Haglund, a pediatric anesthesiologist, established the first medical-surgical pediatric intensive care unit (PICU) for infants and children at the Children's Hospital in Göteborg in Sweden.

In France, in 1963, a newborn presented with tetanus and was admitted to l'Hôpital des Enfants Malades of Paris. Shortly afterward, Dr. Gilbert Huault and J.B. Joly, both neonatologists, opened the first multidisciplinary PICU in France at Saint Vincent de Paul Children's Hospital. This unit was the first pediatrician-directed PICU in Europe; it soon became a major influence on the development of PICUs.

In the mid-to-late 1970s, as pediatric cardiovascular surgery for more complex lesions in infants was developing, nurses provided postoperative care in designated units. Children with Reye syndrome suddenly appeared, requiring complex multisystem care. In addition, in the 1980s, emergency medical services (EMS) systems began transporting severely injured children to hospitals, where they required rapid assessment and intervention by nurses and physicians and initiation of cardiorespiratory and neurologic support.

2. Of the following, which most profoundly influenced the development of early distinct, geographically separate, multidisciplinary pediatric intensive care units?

   A. Advanced forms of mechanical ventilation

   B. Federal government finance programs

   C. New therapeutic interventions for oncology patients

   D. Nursing

   Preferred response: D

Rationale

Pediatric critical care medicine (PCCM) developed initially through the efforts of pediatric anesthesiologists, as well as pediatric general and cardiac surgeons, and neonatologists. In fact, most of the original PICUs were founded by pediatric anesthesiologists. Before discrete, geographically separate, intensive care units evolved, critically ill children often received close monitoring, intensive nursing care, and pulmonary support in the postanesthetic recovery room.

Chapter 2: High-Reliability PICU: Role of the Intensivist and Team in Obtaining Optimal Outcomes

---

1. The PICU leadership team at your hospital is discussing the results of a recent analysis of a quality and safety benchmark report showing a drop in performance measures over the previous three quarters. The PICU nursing director states that several PICUs have improved quality by learning from so-called high-reliability organizations. Which of the following industries are commonly cited as high-reliability organizations?

   A. Coal mining

   B. Commercial aviation

   C. Health care

   D. High-speed passenger railroad

   Preferred response: B

Rationale

The most commonly cited examples of high-reliability organizations include U.S. Navy aircraft carrier flight deck operations, commercial aviation, nuclear power, and wilderness/forest firefighting. Whereas many health care organizations certainly aspire to become high-reliability organizations, there are few examples (if any) of high-reliability organizations in health care today.

2. High-reliability organizations are characterized by five core principles. Which of the following is a core principle of all high-reliability organizations?

   A. Commitment to resilience

B. Deference to hierarchy (“command and control”)

C. Lack of transparency

D. Preoccupation with success

Preferred response: A

Rationale

The five core principles of high-reliability organizations include deference to expertise, reluctance to simplify, sensitivity to operations (which often means greater transparency), preoccupation with failure (and learning from failures), and commitment to resilience.

Chapter 3: Subspecialization Within Pediatric Critical Care Medicine

---

1. Which of the following conditions is in conflict with the American Board of Pediatrics’ criteria for establishing a new subspecialty?

A. The discipline will contribute new information and advance research in the field.

B. The new subspecialty has a unique body of knowledge and a scientific basis.

C. The subspecialist will provide complex tertiary care.

D. The subspecialist will replace the general pediatrician in providing continuity of care.

Preferred response: D

Rationale

The American Board of Pediatrics’ criteria for establishing a new subspecialty seek to assure that children will be better served by the establishment of the new subspecialty and that the new subspecialists will teach the content of the new discipline to learners at all levels, provide consultation to other practitioners, supply special complex care, and create new knowledge in the discipline through research.

2. Which of the following statements reflects the current state of subspecialization in pediatric critical care?

A. Both cardiac critical care and neurocritical care have demonstrated improved patient survival related to stand-alone ICUs.

B. Continuous exposure to (sub) subspecialty patients is a more effective education strategy than intermittent experience in subspecialty ICUs.

C. Subspecialty ICUs provide opportunities for research to determine best care practices for specific patient groups.

D. The American Board of Pediatrics currently recognizes two subsubspecialties of pediatric critical care medicine.

Preferred response: C

Rationale

At present it is not possible to draw an adequately informed conclusion about the value of further subspecialization within pediatric critical care medicine or even to affirm the value of existing almost subsubspecialties. Data related to their current impact or their likely future impact on patient outcomes or educational results remain limited. From a health policy perspective, whether the trend toward further subspecialization advances the goals of improving medical care, impacting population health, and managing cost remains to be determined. It does appear that the existing subsubspecialty groups are facilitating research by bringing problems of particular importance for certain patient groups into clearer focus and drawing interested investigators into more coherent groups (eg, CHN, PNCRG) that are able to address them. It may be that identification of best practices and results of this research disseminated to the pediatric critical care medicine community as a whole will be the most important outcome of limited additional subspecialization.

To date, evidence does not demonstrate improved survival based on the cardiac ICU versus PICU model of postoperative care. The only studies to date examining the relationship between models of postoperative intensive care and outcome found no relationship overall between mortality, length of stay, or complications (including cardiac arrest, mechanical circulatory support, arrhythmias acute, respiratory insufficiency requiring reintubation or prolonged mechanical ventilation, renal failure requiring renal replacement therapy, new seizures or neurologic deficit, or infection), and the model of care.

It is not known whether *bolus* doses of focused subsubspecialty care rather than a steady infusion of caring for similar patients over 3 years results in better retention of knowledge and skills. Even if both have the potential to be similarly effective in achieving a steady state, the half-life of knowledge that results from intermittent exposure is unknown.

Chapter 4: Critical Communication in the PICU

---

1. Which is an important factor in the successful implementation of huddles?
   A. Designating a leader
   B. Encouraging the elective participation of team members
   C. Holding the huddle in a remote location
   D. Performing on an ad hoc basis
   Preferred response: A

Rationale

- All huddles should be led by a designated leader to keep the discussions brief and focused.
- Mandatory participation of all team members is required for a successful huddle.

- Huddles should be held in a central location to encourage all team members to attend.
- Huddles should be incorporated in an institution's standard work.
- The duration of huddles should be 10 minutes or less, whenever possible.

2. What is the focus of team training programs?
   A. Avoiding errors during training to prevent confusion
   B. Developing communication strategies that promote hierarchy among team members
   C. Emphasizing individual tasks, duties, and responsibilities
   D. Facilitated debriefings
   Preferred response: D

Rationale

- Team training programs focus on facilitated debriefings to transform experiences into retained knowledge.
- Members are encouraged to learn all team tasks, duties, and responsibilities.
- Incorporating errors during training allows for the creation of contingency plans.
- The focus of communication strategies is to flatten hierarchy and encourage assertiveness.
- Closed-loop communication maintains a shared mental model among all team members.

Chapter 5: Professionalism in Pediatric Critical Care

---

1. Which of the following best describes the Charter on Medical Professionalism?
   A. It depicts the good and virtuous doctor.
   B. It focuses on putting the patient first.
   C. It portrays professionalism as a social contract.
   D. It recognizes the patient's right to access all medical resources.
   Preferred response: C

Rationale

The charter sets forth a social contract by which professionals justify the privileges of their profession by performing as professionals. It lays out principles that underlie 10 commitments of physicians to patients and society. It is not a description of the good and virtuous doctor. All recognize that doctor by his or her behaviors toward patients and others. It views the social contract in the context of the "medical marketplace" and social and financial pressure. Although it emphasizes altruism

and putting the patient first, it goes well beyond that in defining broad commitments to society. The charter recognizes the patient's right to make informed choices among the available options, but it also lays out commitments under which the physician distributes finite resources equitably and informs patients honestly and as completely as possible so that they can choose wisely.

2. Which is true of the Physician Charter?
   A. It describes professional responsibilities.
   B. It expresses ethical values.
   C. It mandates professional behaviors.
   D. It sets guidelines for regulatory agencies.
   Preferred response: A

Rationale

The charter describes the responsibilities that fulfill the physician's professional contract with society. It does not have the force of law and has no power to mandate professional behavior. It does not reduce physician responsibilities to guidelines for actions. It is not so much a statement of ethical values as it is a commitment to 10 practical physician responsibilities.

Chapter 6: Nurses in Pediatric Critical Care

---

1. Dr. Linda Aiken has conducted research examining nurse staffing and patient outcomes. Her findings support the observation that nursing leaders have at least three major opportunities to boost nurse retention and patient outcomes. These opportunities include the following:
   A. Conducting research, decreasing numbers of support personnel, and forming relationships with schools of nursing
   B. Developing policies, increasing numbers of support personnel, and enhancing teamwork in the unit
   C. Increasing nurse staffing, using a more highly educated nurse workforce, and enhancing the work environment
   D. Increasing numbers of staff meetings, developing policies, and having recognition celebrations
   Preferred response: C

Rationale

Dr. Linda Aiken's work demonstrated that having enough highly educated staff members and a healthy work environment will have a great impact on nurse and patient outcomes. Numerous studies in the literature establish that healthy work environments are critical to good outcomes. The other answers do not list all components that would necessarily improve the work environment.

2. A 3-year-old boy who was admitted to the PICU with a traumatic brain injury has evolved to brain death. A family meeting has taken place, and support will be withdrawn. Comfort care is being provided, and the patient's nurse arranges for family and visitors to say goodbye to the boy one last time, even though the group is very large. This is an example of which nurse competency from the synergy model?
   A. Advocacy/moral agency
   B. Clinical inquiry
   C. Collaboration
   D. Facilitation of learning
   Preferred response: A

Rationale

When a cure is no longer possible, nurses turn their focus to ensuring that death occurs with dignity and comfort. Nurses support parents and family members through the death of their loved one. Nurses often coordinate the experience for patients and families when death is imminent. The other competencies may apply in this situation, but the primary one is advocacy/moral agency.

Chapter 7: Research in Pediatric Critical Care

---

1. Surrogate end points are frequently used to make pediatric critical care trials feasible. Which of the following statements about surrogate end points for pediatric clinical trials is true?
   A. A variable that is correlated with a clinically meaningful end point will be a good surrogate end point for a clinical trial.
   B. A variable that is implicated in the causal pathway for a clinically meaningful end point will not be a good surrogate end point for a clinical trial.
   C. Surrogate end points are not useful for pediatric critical care trials because oftentimes the number of true clinically meaningful events may be small.
   D. Surrogate end points can be used to decrease the lost-to-follow-up rates.
   Preferred response: D

Rationale

- Surrogate end points are useful for pediatric critical care trials because oftentimes the number of true clinically meaningful events may be small.
- Surrogate end points should not only be correlated with the clinically meaningful end point but should be implicated in the causal pathway. Otherwise a change in the surrogate end point may not translate to a change in the clinically important end point (eg, a statin drug to lower cholesterol may not ultimately lower the rate of cardiovascular death).

- Surrogate end points are useful for pediatric critical care trials because oftentimes the number of true clinically meaningful events may be small.
- Composite surrogate end points (such as ventilator free days) combine two or more clinical end points.
- A variable that is implicated in the causal pathway for a clinically meaningful end point will be a good surrogate end point for a clinical trial.

2. An adult critical care randomized controlled trial has recently demonstrated a 30% relative risk reduction of mortality for a new sepsis drug. Which of the following is not an important factor when considering the generalizability of these findings to critically ill children with sepsis?
   A. Different rates and types of comorbidities in adults versus children with sepsis
   B. Different rates of sepsis among adults and children
   C. Potentially different pathophysiology of pediatric versus adult sepsis related to developmental issues in children
   D. Practice variation between adult and pediatric critical care with regard to other aspects of managing patients with sepsis

   Preferred response: B

Rationale

Although there are different rates of sepsis between adults and children, the therapy will be applied only to those with sepsis. There may be differences between the definitions of sepsis between adults and children, which affect the heterogeneity of the disease processes, but the rates themselves are not as important when considering the generalizability of treatment with a specific drug for a population of patients identified with sepsis. Preexisting comorbidities may have an important impact on the potential treatment effect for the new drug, which may differ between adults and children. The innate immune response likely differs as a function of development, and it may lead to different treatment effects in children compared to adults, or even among children. Answer C is a true statement given potential differences in other confounding variables that affect sepsis mortality between adult and pediatric critical care.

3. Which of the following is true about null hypotheses?
   A. Experiments should be designed to prove the null hypothesis.
   B. In medical research, it is rarely necessary to formulate a null hypothesis.
   C. Rejection of the null hypothesis proves the counter hypothesis.
   D. When reasoning from inferences, formulation of the null hypothesis is necessary.

   Preferred response: A

Rationale

The null hypothesis is a falsifiable hypothesis that is experimentally tested, and when it is not supported (ie, falsified), the result is considered to support the hypothesis (research hypothesis or alternative hypothesis). For example, if a

researcher is trying to determine whether a drug improves the outcome from a given disease, a null hypothesis would be that treatment with the drug has no effect. If experimentation demonstrates a statistically valid effect, the null hypothesis is rejected and this finding supports (but does not prove) that the hypothesis is tenable. All hypotheses testing in medicine is the testing of null hypotheses. Inferential reasoning is not statistically testable; it may be used to generate hypotheses that can be tested, but reasoning by inference depends on correct facts to make correct conclusions.

4. When comparing populations that demonstrate both skewness and kurtosis, which is true?
   A. A student *t* test is adequate for two distinct populations.
   B. Data that demonstrate significant kurtosis cannot be transformed for parametric statistical analysis.
   C. Nonparametric tests may be necessary for statistical analysis.
   D. Sample size is less important than when comparing populations with categorical variables.

   Preferred response: C

Rationale

Parametric statistical tests apply to samples drawn from a population with a known distribution. In medicine the distribution is assumed to be Gaussian or normal distribution (the bell-shaped curve). The distribution is symmetrical around the mean, with 99.7% of the distribution lying within three standard deviations of the mean. Skewness describes asymmetric distribution, and kurtosis defines how sharp the *peak* of the distribution is—that is, how much of the data are close to the mean.

Skewed or kurtotic medical data are not normally distributed and cannot be tested by parametric statistical analysis. The *t* test is for normally distributed data. Medical data often are not normally distributed. Transformation of nonparametric data by correcting for either skewness or kurtosis can render nonnormally distributed data analyzable by parametric tests. Response C is correct because nonnormally distributed data require nonparametric statistical tests.

Chapter 8: Proving the Point: Evidence-Based Medicine in Pediatric Critical Care

---

1. A randomized controlled trial of 100 children with meningococcemia compared compound X to placebo. Children receiving compound X had a 28-day mortality of 20% (versus 30% in children receiving placebo, $p = 0.36$). Which of the following would make you *most* concerned that the study was not adequately powered?
   A. Only 30% of subjects meeting inclusion criteria were successfully enrolled.
   B. The sample size was determined based on an estimated change in mortality

from 36% in the placebo arm to 10% in the compound X arm.

C. The trial was funded by the company that makes compound X.

D. This was the first randomized controlled trial (RCT) of compound X, so sample size calculations were based on observational studies.

Preferred response: B

Rationale

Power is directly related to sample size and the size of treatment effect, with larger sample sizes and larger effect sizes increasing power. In this case, the size of the treatment effect was smaller than anticipated, meaning that sample size calculations based on the anticipated effect size would have overestimated the study's power.

Questions 2 and 3 Refer to the Following Study.

A randomized controlled trial of compound X versus placebo for pediatric septic shock enrolled 1000 children with septic shock. Subjects receiving compound X had a 28-day mortality of 10% (versus 15% in children receiving placebo, $p = 0.017$).

2. How many children need to be treated with compound X to prevent one death (ie, what is the number needed to treat)?

   A. 1.5

   B. 6.67

   C. 15

   D. 20

   Preferred response: D

Rationale

Number needed to treat is 100 divided by the absolute risk reduction. In this case, 100/(15%−10%) = 100/5 = 20.

3. What is the relative risk of mortality with compound X versus placebo?

   A. 0.05

   B. 0.10

   C. 0.67

   D. 1.5

   Preferred response: C

Rationale

Relative risk is the ratio of two probabilities. In this case, it is the probability of death with compound X (10%) divided by the probability of death with placebo (15%): 0.10/0.15 = 0.67.

4. During the past 2 years, lower extremity deep venous thrombosis (DVT) developed in 20 of 1000 infants undergoing mechanical ventilation. An investigator hypothesizes that femoral venous central lines are contributing to the

development of DVT. To test this hypothesis, the investigator compares the use of femoral lines in the 20 infants with DVT to the use of femoral lines in 50 of the infants in whom DVT did not develop. She finds that 10 of 20 infants with DVT had a femoral line, and 10 of 50 infants without DVT had a femoral line. What type of study is this?

A. Before-and-after study

B. Case-control study

C. Randomized controlled trial

D. Retrospective cohort study

Preferred response: B

Rationale

In a case-control study, cases are selected based on the outcome (in this scenario, DVT) and compared with control cases in which the outcome did not develop to determine factors associated with the outcome. Case-control studies are commonly used to study uncommon outcomes (such as DVT developing in only 2% of infants in this scenario).

Cohort studies include all subjects with a given exposure. In this scenario, a cohort study would have included all 1000 ventilated infants. Case series tend to be descriptive reports of a small number of subjects with a common exposure or diagnosis. Before-and-after studies are usually cohort studies that use historical controls and are designed to assess the effect of the widespread use of a new treatment or organization in care. In an RCT, subjects are randomly assigned to an intervention or control group.

5. Which of the following studies would provide the highest level of evidence?

A. A case-control study of 350 subjects

B. A cohort study of 10,000 subjects

C. A report of 3 subjects surviving a previously universally fatal condition after receiving a newly developed medication

D. A report of 15 subjects receiving a new ventilator strategy

Preferred response: C

Rationale

Response C describes *all or none* evidence, which is level 1c evidence. Large cohort studies and small RCTs provide level 2 evidence. Response D describes a case series, which is level 4 evidence.

Chapter 9: Prediction Tools for Short-Term Outcomes Following Critical Illness in Children

1. A researcher develops a model to predict the risk of patients admitted to the PICU of developing a deep venous thrombosis based on a number of demographic and clinical factors. The model is developed on 1000 patients with an area under the receiver operating characteristic curve (AUC) of 0.8. The model is subsequently validated on a separate dataset of 1000 patients with an AUC = 0.7. What term best describes the model's performance as quantified by the AUC?

   A. Calibration

   B. External validity

   C. Discrimination

   D. Internal validity

   Preferred response: C

Rationale

Discrimination is the accuracy of a model in differentiating outcomes groups and is most often assessed by the AUC. External validity is the extent to which the results of a study can be generalized to other situations and other people. External validity is typically assessed through the process of study replication. Calibration refers to the ability of a model to assign the correct probability of outcome to patients over the entire range of risk prediction. The most accepted method for measuring calibration is the Hosmer-Lemeshow goodness-of-fit test. Internal validity relates to the extent to which a causal conclusion based on study findings is warranted and is assessed by the degree to which the study design minimized systematic error or *bias*. The precision of a measurement system is the degree to which repeated measurements under unchanged conditions show the same results.

2. A previously healthy 7-year-old-male is admitted to the PICU of a tertiary care children's hospital in septic shock secondary to lobar pneumonia. He is tachycardic (heart rate, 130 beats per minute) and tachypneic (respiratory rate, 55 breaths per minute) and undergoes intubation of the trachea within 30 minutes of PICU admission for respiratory failure. Arterial blood gas reveals pH = 7.2, $PaCO_2$ = 40 mm Hg, PaO_2 = 80 mm Hg, and HCO_3^- = 12 mEq/L on FiO_2 of 0.6. Coagulation studies reveal an elevated INR = 1.8. Which scoring system is *most* appropriate to assess this patient's physiologic status on the initial day of PICU admission?

   A. PELOD

   B. PRISM III

   C. SNAPPE-II

   D. STS-EACTS score

   Preferred response: B

Rationale

CRIB II and SNAPPE-II are scoring systems for neonates. STS-EACTS score was developed for patients with congenital heart disease. PELOD is a scoring system designed to quantify the degree of organ dysfunction in PICU patients and correlates well with mortality. PELOD, however, is calculated based on the greatest degree of physiologic dysfunction to occur at any point during the entire PICU admission, not

just the initial day of admission. PRISM III is a physiology-based acuity score that is calculated in the interval from the 2 hours preceding PICU admission to 4 hours following PICU admission.

3. You are asked to accept the transfer of a 2-year old child with respiratory failure secondary to viral pneumonitis from a rural emergency department (ED). The child was seen and discharged from that ED 2 days ago. This morning, her parents awoke to her loud breathing and called emergency medical services. The emergency medical technicians assessed the child, determined that she had respiratory failure, stabilized her airway, provided bag-valve-mask ventilation with oxygen, and provided respiratory treatments during transport to the local ED. They notified the ED of the child's condition. The ED is performing additional steps for stabilization, along with some diagnostic tests, including a chest radiograph and basic laboratory studies. The ED has explained to the family that their child will need to be transported to the local children's hospital, and someone from the ED is calling you for a helicopter transport. This scenario demonstrates appropriate system design for the critically ill child around which of the following issues?

   A. Access

   B. Cost

   C. Outcome

   D. Process

   Preferred response: A

Rationale

Systems are designed to facilitate easy access to services for those who need them. Access (response A) describes organized and integrated care for critically ill children and their families who are in need of tertiary pediatric services. Cost (response B) is an important element of health care delivery that focuses on the monetary resources devoted to patient care. However, economic terms are not discussed in this scenario. Research is an important activity in generating new knowledge, but this scenario is concerned with the delivery of care to an individual patient. Although the child ultimately may be enrolled in a research project or database evaluating outcomes, research is not the primary focus of her care. Process measures (response D) are those that occur between patients and providers or between various providers. Although a number of clinical processes have occurred in the scenario, the scenario also includes a number of interactions between other structural components, such as institutions and emergency services, which establish an organized hierarchy of interactions for the delivery of care. The final outcomes of care from the ICU perspective (response C) are not discussed in the scenario. Although the child was effectively rescued and delivered to the rural ED and a number of intermediate outcomes may be described, the final outcomes in terms of vitality, economics, or morbidity are yet to be determined. Therefore the most appropriate answer is A.

4. After the first ICU day, the child's PRISM III score is 8. What should you do?

   A. Ignore the score for today.

   B. Remove the child from mechanical ventilation and provide comfort care.

C. Rescore the patient using the Pediatric Index of Mortality (PIM).

D. Recognize that this score is correlated with a population risk of mortality.

Preferred response: D

Rationale

The PRISM score is a physiologically based severity of illness measure calculated from variables determined within the first 24 hours of care. It is helpful for understanding the risks for mortality and length of stay for populations of patients with a given severity of illness. However, the score cannot be applied for prognostication at the level of individual patients; hence it should not be used to guide clinical decisions as suggested in response B. Repetitive scoring using PRISM during hospitalization (response A) has not been validated. Using the PIM (response C), which captures care at the point of admission rather than at 24 hours, provides a different measure of severity that also can be compared across populations. Importantly, a bias exists in relation to the inclusion of mechanical ventilation as a predictor variable in PIM. Therefore the most appropriate answer is D.

Chapter 10: Long-Term Outcomes Following Critical Illness in Children

---

1. Which of the following characteristics is incorrectly included in an ideal health-related quality of life (HRQL) instrument?

   A. Interpretability of HRQL scores

   B. Proxy report as the gold standard

   C. Psychometric properties

   D. Responsiveness or sensitivity to change

   Preferred response: B

Rationale

The gold standard for a quality of life assessment is self-report. However, children may be too young or too disabled to provide this assessment. All of the other choices represent important considerations in a health-related quality of life assessment tool.

2. Which of the following statements accurately characterizes a long-term outcome assessment of PICU survivors?

   A. It should include involvement of pediatric intensivists, pulmonologists, and psychologists.

   B. It should be focused primarily on physical recovery.

   C. It should defer family-related issues to the family's primary care physicians.

   D. It should largely minimize preexisting, comorbid conditions present prior to PICU admission.

Preferred response: A

Rationale

Follow-up for critical illness survivors is likely to benefit from a multidisciplinary approach. All aspects of a patient's health-related quality of life should be assessed. Families as well as patients may exhibit aspects of post–intensive care syndrome.

3. A clinician would like to serially assess a child's overall functional status during and following an episode of meningococcal sepsis. Which of the following would be the most appropriate tool for this purpose?

   A. Functional Status Scale

   B. Pediatric Cerebral Performance Category

   C. Pediatric Index of Mortality

   D. Pediatric Quality of Life Inventory

   Preferred response: A

Rationale

The Functional Status Scale was specifically designed to quantify functional status. Item C provides estimates of illness severity and item D assesses health-related quality of life. Item B (PCPC) provides an assessment of neurologic status for the Pediatric Overall Performance Category Score (a gross estimate of functional status), but it does not assess overall functional status.

Chapter 11: Safety and Quality Assessment in the Pediatric Intensive Care Unit

---

1. Which of the following is true of root cause analysis (RCA), a tool used in both safety and quality investigations?

   A. Root cause analysis applies proactive inquiry.

   B. Root cause analysis leads to the single root cause.

   C. Root cause analysis is prone to hindsight bias.

   D. Root cause analysis asks the question "how?" five times.

   Preferred response: C

Rationale

Root cause analysis is a retrospective tool used to ideally find all contributing causes (not one cause) that led to an adverse event. RCA involves asking "why?" five times, and answers are recorded in fishbone or Ishikawa diagrams. Because of the retrospective nature of RCAs, they are prone to hindsight bias.

2. In contrast to Safety I approaches to improving patient safety, which of the

following statements is true of Safety II?

A. Safety II presumes health care systems are well understood.

B. Safety II strives to reduce variation as the source of failures.

C. Safety II knows policies are correct and complete.

D. Safety II applies proactive, preventive methods.

Preferred response: D

Rationale

In contrast to Safety I, which presumes health care systems are well understood with correct and complete policies that would yield safe outcomes if people would only comply and reduce variation, Safety II proactively seeks to promote adaptation by people to dynamic, poorly understood, and complex systems to prevent future events.

Chapter 12: Information Technology in Critical Care

1. The Health Information Technology for Economic and Clinical Health Act (HITECH Act) was enacted by the US Congress under what act?

   A. American Recovery and Reinvestment Act (ARRA)

   B. Children's Health Insurance Program Reauthorization Act (SCHIP)

   C. Health Care and Education Reconciliation Act

   D. Patient Protection and Affordable Care Act

   Preferred response: A

Rationale

The Health Information Technology for Economic and Clinical Health Act (HITECH Act) was enacted under Title XIII of the American Recovery and Reinvestment Act of 2009 and carries a commitment of up to $27 billion to improve the US health information technology infrastructure. The HITECH Act outlined the plans for incentivizing the implementation and meaningful use of electronic health records (EHRs) through the Centers for Medicare & Medicaid Services EHR Incentive programs.

2. The acronym "PCORI" stands for which of the following?

   A. Patient-Centered Outcomes Research Institute

   B. Patient Collaborative on Research Informatics

   C. Pediatric Critical Care Organization for Research Investigations

   D. Personal Care and Outcome Records Initiative

   Preferred response: A

Rationale

The Patient-Centered Outcomes Research Institute (PCORI) was created under the Affordable Care Act of 2010 to promote comparative effectiveness research across the United States. PCORnet, the National Patient-Centered Clinical Research Network, is a PCORI-based initiative to create a large, highly representative network for conducting clinical outcomes research. PCORnet's proposed infrastructure is composed of 11 health system–based networks and 18 patient group–based networks, and its goal is to generate interoperable datasets to support multinetwork observational and randomized clinical studies.

3. Which statement about safe computing practices is true?
   A. A password that is eight characters or longer, includes upper and lowercase letters, and includes at least one number or nonalphanumeric symbol can be considered strong.
   B. Protected health information may be stored on laptops or removable media such as flash drives.
   C. Recycling two strong passwords is acceptable if it is done every 4 weeks.
   D. Virus definitions for antivirus software should be kept up to date, and security updates of software, especially operating systems, email clients, and web browsers, do not need to be installed every time they become available.

   Preferred response: A

Rationale

- Weak passwords can open the entire network to attack by hackers.
- Passwords should never be recycled.
- Strong passwords are longer than six characters, include upper and lowercase letters, and include at least one number or nonalphanumeric symbol.
- Security updates of software are developed to address specific threats recently identified and should be installed to protect your system from them.
- Protected health information must be encrypted if it is not stored on secure devices on secure networks.

4. Which of the following statements regarding electronic health records is true?
   A. Clinicians who will use the electronic health record should be vocal participants during its selection, development, and implementation.
   B. Computerized physician order entry eliminates medication errors.
   C. Implementation of an electronic health record reduces workload and enhances communication among caregivers.
   D. Policies, procedures, and workflow that work well in a paper system should be ported in their entirety into a paperless system.

   Preferred response: A

Rationale

- Computerized physician order entry systems eliminate some medication errors such as those associated with illegibility but can create new types of errors while

leaving other types of errors unaffected.

- Changing to a paperless system will reengineer processes either by accident or on purpose. Policies, procedures, and workflow that work in a paper system can never be ported wholesale.
- The electronic health record usually increases the workload of physicians and nurses. It may or may not enhance communication. It will certainly change the way team members communicate.
- Clinicians who do not advocate for their own needs will almost certainly be disappointed in the result, and dissatisfied users will limit the success of the implementation.
- Excessive clinical alerts that disrupt workflow can impede care and induce clinicians to ignore all alerts.

Chapter 13: Building Partnerships: Patient- and Family-Centered Care in the Pediatric Intensive Care Unit

1. Which of the following practices is *not* a fundamental approach to patient- and family-centered care?

   A. Developing partnerships based on mutual respect with patients and families to establish professional boundaries and roles within the relationship

   B. Incorporating patients and families in the development of hospital policies and procedures to adequately meet the needs of patients and families

   C. Practicing cultural humility and using cultural navigators, when available, to gain a better understanding of the cultural context of the child

   D. Protecting parents from experiencing emotional distress by prohibiting them from being present with their children during cardiopulmonary resuscitation and highly invasive procedures

Preferred response: D

Rationale

A, B, and C are all fundamental aspects of patient- and family-centered care. However, removing parents and caretakers from their children during cardiopulmonary resuscitation and highly invasive procedures can lead to a higher level of distress and emotional trauma. Allowing choice in family presence during cardiopulmonary resuscitation and invasive procedures has direct benefits for parents, including improved satisfaction, better understanding, reduced anxiety, better coping, more emotional stability, and improved adjustment to a child's death.

2. Which of the following is true regarding family-centered rounds?

   A. Breach confidentiality by exposing protected health information

   B. Prevent teaching of trainees

   C. Require extensive planning for successful implementation

   D. Undermine the trusting relationship between families and health care providers

   Preferred response: C

Rationale

Despite concerns raised by health care providers, family-centered rounds improve the quality of care provided, potentially reduce length of stay, build trusting relationships between health care providers and families, allow additional opportunities for teaching trainees, and do not breach confidentiality of protected health information if executed using a thoughtful and planned approach.

3. In general, what is the primary cause of stress in parents related to the admission of their child to an ICU?

   A. They are concerned about the cost of care.

   B. They are afraid their child will die.

   C. They are stressed about being separated from their child.

   D. They are concerned their child will not be the same after leaving the hospital.

   Preferred response: C

Rationale

The admission process can be frightening for the parents and child, especially when the admission is emergent or unplanned. Every effort should be extended to help the parents acclimate to the new environment; they should be treated with compassion and courtesy, and time should be taken to meet their needs. Parents report a loss of control, which can be unbearable when they are separated from their ill child. To support the child and the parents, caregivers should invite the parents to be part of the admission process and enable them to remain with their child to the extent possible.

Chapter 14: Ethics in Pediatric

Intensive Care

1. Which of the following is a true statement regarding the doctrine of informed consent?
   A. Decisions must be voluntary and not subject to coercion, manipulation, or undue influence.
   B. It does not apply to decisions involving research.
   C. The patient needs to understand all the minutia of the treatment being discussed.
   D. The decision making should be shared with a competent medical provider.
   Preferred response: A

Rationale

The doctrine of informed consent applies to both medical decisions and research. Informed consent must satisfy four requirements that apply when surrogates provide permission as well as when consent is obtained directly from patients. With *disclosure,* the clinician should supply the patient with sufficient information that a "reasonable person" would desire to be able to make an informed medical decision. With *understanding,* the clinician should assess the patient's understanding of the proposed course of action, the risks and benefits of that course of action, and any available alternatives along with the risks and benefits associated with those actions. Understanding may be particularly impaired in the critical care setting where the high stakes and time pressures can impact the ability to achieve optimal understanding. With *capacity,* the patient must meet legal requirements for competency, be able to understand the medical decision, form a reasonable judgment based on the consequences of the decision, and be able to communicate that decision to others. Legally, children under the age of 18 are not considered competent for medical decision making with the exception of emancipated and mature minors. *Emancipated minors* are considered competent based on characteristics that are defined by state law, but may include pregnancy, parenthood, or establishing financial independence. *Mature minors* represent another category that is defined by state law whereby a minor, usually above a certain age, can be judged competent to make certain medical decisions. Most states require a judge to make these determinations, and the judge may restrict the determination to the medical decisions at hand. With *voluntariness,* decisions must be voluntary and not subject to coercion, manipulation, or undue influence. Importantly, physicians should not withhold or deemphasize information in an effort to manipulate patients.

2. Which of the following is an important consideration that may justify seeking legal intervention to override a parent's decision to refuse a medical therapy?
   A. Mediation and negotiation efforts are initiated and conducted by the state courts.
   B. Parental authority is absolute and cannot be challenged legally by medical professionals.

C. The intervention refused by the parent is one that is not commonly performed.

D. The parent's decision places the child at a significant risk of serious harm.

Preferred response: D

Rationale

In most situations, parents are granted wide latitude in the decisions they make on behalf of their children, and the law has respected those decisions except when they place the child's health, well-being, or life in jeopardy. Parental authority is not absolute, however, and when a parent or guardian fails to adequately guard the interests of a child, the decision may be challenged, and the state may intervene. A clinician's authority to interfere with parental decision making is limited. Except in emergency situations where a child's life is threatened imminently or a delay would result in significant suffering or risk to the child, the physician cannot do anything to a child without the permission of the child's parent or guardian. Touching (physical examination, diagnostic testing, or administering a medication) without consent is generally considered battery under the law. The clinician's options include either tolerating the parents' decision (while continuing to try to convince them to act otherwise) or involving a state agency to assume medical decision-making authority on behalf of the child.

Only the state can order a parent to comply with medical recommendations. This can take different forms, but most frequently either includes involvement of child protective services (under a claim of medical neglect) or a court order. Both of these options represent a serious challenge to parental authority, and parents will generally perceive them as disrespectful and adversarial. Such action interferes with family autonomy, can adversely affect the family's future interactions with medical professionals, and can negatively impact the emotional well-being of the child. Neither should be undertaken without serious consideration. Before initiating the involvement of state agencies to limit parental authority and override parental refusal, the clinician must establish that (1) the recommended course of action is likely to benefit the child in an important way, (2) the treatment is of proved efficacy with a reasonable likelihood of success, (3) the parent or surrogate's decision to refuse intervention places the child at *significant* risk of *serious* harm in comparison to the recommendations of the health care team (applying the *harm principle*), and (4) all attempts at mediation and negotiation to find a mutually acceptable solution have been exhausted.

Chapter 15: Ethical Issues in Death and Dying

---

1. A family member requests the ongoing use of extracorporeal membrane oxygenation (ECMO) in an infant with irreversible lung disease and severe hypoxic-ischemic encephalopathy and no other options for therapy (eg, lung transplant). Initially, what is the most appropriate way to proceed with this case?

   A. Attempted declaration of physiologic futility of the therapy to support

unilateral withdrawal of ECMO

B. Immediate involvement of legal services to determine the availability of legal options to support cessation of therapy

C. Intensive communication with the family members involving all of their providers, psychosocial and spiritual support, and the ethics committee in attempts to reach consensus with the family

D. Separation from ECMO when the family is not around

Preferred response: C

Rationale

The patient's family is requesting the ongoing use of a therapy that is possibly inappropriate. As true futility distinctions are difficult to make and unlikely to be possible in this case (ie, ECMO is physiologically "working" here) and rationing of care based on case is not recommended ad hoc for an individual patient, the most appropriate initial course for this patient is to focus on multidisciplinary communication efforts with the family in an attempt to reach consensus. Involvement of legal services would not be appropriate prior to aggressive attempts at communication and involvement in hospital processes first. It would never be appropriate to do something without the family knowing.

2. Which of the following actions is the least morally permissible when treating a patient at the end of life?

A. Administration of a neuromuscular blocking agent when extubating a patient

B. Palliative sedation

C. Withdrawal of ventilatory support

D. Withholding of enteral feeding and intravenous (IV) fluids

Preferred response: A

Rationale

The withdrawal and withholding of life-sustaining therapies are equally justifiable when care is redirected to focus on comfort. This includes ventilatory support as well as feeding and hydration. The doctrine of double effect supports the use of analgesia and sedation at the end of life when the intent is to treat pain and suffering. The use of neuromuscular blockade as support as being withdrawn is arguably morally indefensible as it offers the patient no relief or comfort except for potentially hastening the dying process. It may also interfere with the ability to recognize and treat a patient's suffering.

3. Regarding life-sustaining medical treatment (LSMT), what did the President's Commission on Ethical Problems in Medicine conclude?

A. Withdrawing LSMT is morally preferable to withholding it.

B. Withholding LSMT is morally preferable to withdrawing it.

C. Withholding and withdrawing LSMT are morally equivalent.

D. Withholding and withdrawing LSMT are morally equivalent to killing.

Preferred response: A

Rationale

A strong consensus in ethics and law holds that no meaningful distinction exists between withholding and withdrawing life-sustaining treatment. However, the President's Commission on Ethical Problems in Medicine[1] concluded that contrary to widespread feelings on the matter, withdrawing treatment is preferable to withholding it for two reasons. First, withdrawing treatment implies there has been more time to assess the prognosis and the likelihood of a successful outcome. It comes after a clinical trial. Good ethics start with good facts, and a decision to withhold treatment generally is made with fewer data than is the decision to withdraw it after treatment has been tried. Second, a tradition of reluctance to withdraw treatment often has led to inappropriate withholding of support from patients who, in retrospect, possibly had a good chance for meaningful long-term survival. One common setting was the delivery room, where high-risk infants sometimes were not resuscitated because of the fear that treatment would succeed in the medical sense but that the infant's prognosis for meaningful survival would vanish without any means of reversing the decision to treat. Allowing treatment to be stopped allows all patients to enjoy the potential benefits of initial intervention and the possibility of success. The central ethical issue is whether treatment serves the interests of the patient. If it does not, whether it is being considered or has already been tried is irrelevant.

4. What has the Centers for Medicare and Medicaid Services ruled regarding the Emergency Medical Treatment and Labor Act?
   A. It applies to inpatients and outpatients.
   B. It applies only to patients in emergency departments.
   C. It applies only to women in labor.
   D. It does not apply to inpatients.
   Preferred response: D

Rationale

The Emergency Medical Treatment and Active Labor Act was passed in 1986 as a part of the Consolidated Omnibus Budget Reconciliation Act. It is a federal statute that requires participating hospitals (ie, those that accept payment from the Centers for Medicare and Medicaid Services) and ambulances to provide emergency care to all individuals in need. It does not apply to inpatients.

5. Which of the following patients meet standard (“Harvard”) criteria for brain death?
   A. Those who have lost all brain function
   B. Those who have lost all cortical function but sometimes retain brain stem function
   C. Those who are more than 7 days old
   D. Those who often have good hypothalamic function
   Preferred response: D

Rationale

The clinical criteria for brain death promulgated by a Harvard committee 20 years ago have come under increasing criticism because it is clear that many patients declared to be brain dead by standard criteria have not lost all brain function, particularly that of the hypothalamus, as evidenced by normal regulation of antidiuretic hormone activity.

Chapter 16: Palliative Care in the Pediatric Intensive Care Unit

---

1. You are caring for a 2-year-old boy, formerly a 26-week premature infant, with chronic respiratory failure due to bronchopulmonary dysplasia, dependent on mechanical ventilation via a tracheostomy tube. He also has global developmental delay and a seizure disorder. He is admitted to the PICU with severe pneumonia, sepsis, and multiorgan dysfunction syndrome. What is the best strategy to begin a discussion of limitation of interventions with the family?
   A. Ask the family to share their understanding of their son's current medical condition, as well as their values, hopes, and goals with regard to their son and his care.
   B. Impress upon the family that the severity of the child's illness and poor overall prognosis do not justify further aggressive life support given the child's underlying developmental delay.
   C. Inform the family that the patient is not going to live through the night.
   D. Present a list of interventions and ask whether or not the family would like them performed.
   Preferred response: A

Rationale

Discussions of this nature should always begin by allowing the family to articulate their understanding of the child's current condition, as well as their hopes, values, and goals for their child overall. After the clinician has heard this information, recommendations for or against various interventions can be made as they pertain to the family's stated goals. Although it is important to ensure that the family understands the severity of illness and poor prognosis, it is not appropriate to make a recommendation against continuing life support based only on the presence of developmental delay. Physicians are poor at predicting the exact time of death for patients, so statements of certainty around death should be avoided. Physicians should avoid presenting families with a “menu” of options for care; rather they should elicit the family's goals and make recommendations for pursuing or limiting

certain interventions based on their stated goals. Physicians must avoid phrases such as “do everything,” as they are nonspecific and imply that “doing” is always the best course of action.

2. Which of the following is true of methadone use for symptom management?
   A. It has a toxic metabolite that can accumulate and lead to seizures.
   B. It has a long and variable half-life, which can lead to accumulation over time.
   C. It is renally excreted and therefore should be avoided in patients with renal failure.
   D. It shortens the QT interval.
   Preferred response: B

Rationale

The half-life of methadone varies from less than 10 hours to greater than 75 hours, depending on a variety of host factors. It can easily accumulate as it is reaching steady state and lead to oversedation and even obtundation. Therefore dosing and titration must be performed carefully. Morphine is renally excreted and should be avoided in renal failure. Meperidine has a toxic metabolite that can accumulate and lead to seizures. Fentanyl is the only opiate available as a transdermal patch. Methadone prolongs the QT interval, and a screening electrocardiogram should be considered prior to its initiation.

3. Just prior to the withdrawal of mechanical ventilation with the intention of allowing the patient to die, guidelines from the Society of Critical Care Medicine advise against administering which class of medications?
   A. Barbiturates opiates
   B. Benzodiazepines
   C. Neuromuscular blocking agents
   D. Opiates
   Preferred response: C

Rationale

Neuromuscular blocking agents have no sedative or analgesic properties and may mask symptoms of suffering at the end of life. Therefore as a general rule, pharmacologic paralysis should be avoided at the end of life.

In most cases, the effect of these agents can be reversed or allowed to wear off within a short period, allowing for the withdrawal of mechanical ventilation in the absence of the confounding effects of paralysis. Patients who have been receiving neuromuscular blocking agents chronically for management of their ventilatory failure occasionally can present a more difficult ethical dilemma. In some situations, restoration of neuromuscular function may not be possible for several days or even weeks, When faced with this problem, the clinician must choose between withdrawal of the ventilator while the patient is paralyzed versus continuation of life support well beyond the point at which the patient and family have determined that the burdens of such treatments outweigh the probable benefits. In this circumstance, it may be preferable to proceed with withdrawal of life support

despite the continued presence of neuromuscular blockade.

Chapter 17: Process of Organ Donation and Pediatric Donor Management

1. Which statement about organ donation is true?
   A. An insignificant number of organs are lost because of inappropriate or poor donor management.
   B. Authorization for donation after circulatory death (DCD) should be obtained from the family after discussions and decisions about end-of-life care have been determined.
   C. Early referral for organ donation to the organ procurement organization (OPO) enhances recovery of organs for transplantation.
   D. The role of the pediatric intensivist ends after providing support for the family during end-of-life care and declaring death because of a potential conflict of interest with organ donation.
   Preferred response: C

Rationale

Donor management should be viewed as a continuum of care provided by the pediatric intensivist and the critical care team from the time of admission to recovery of organs for transplantation. Involvement of intensivists has resulted in better donor management and recovery of more organs with better graft function following transplantation. The discussions and decision to authorize organ donation from DCD donors can only occur after a decision to withdraw medical support has been made. This avoids the perceived ethical conflict that the patient is being allowed to die to recover organs. Authorization must occur from parents or legal guardians.

Early referral for organ donation to the organ procurement organization (OPO) enhances recovery of organs for transplantation. A significant number of organs are lost because of inappropriate or poor donor management. Authorization for donation after circulatory death (DCD) should be obtained from the family after discussions and decisions about end-of-life care have been determined.

2. Which statement about neurologic death in infants and children is true?
   A. Ancillary studies are required to make the diagnosis of neurologic death in infants younger than 1 year of age.
   B. A $PaCO_2$ of 59 mm Hg in a child with acute lung injury who desaturates 3 minutes into the apnea exam is consistent with brain death.
   C. Neurologic death can be determined in term newborns at 37 weeks' estimated gestational age.
   D. The revised pediatric brain death guidelines require two separate examinations

and a single apnea test to determine neurologic death in infants and children.

Preferred response: C

Rationale

Determination of neurologic death can occur in a term infant at 37 weeks' estimated gestational age (EGA) to 30 days of age. It can be more difficult to make a determination of neurologic death in the neonate; therefore serial examinations are essential to ensure that the clinical examination remains consistent throughout the observation and testing period. The recommended observation period for infants at 37 weeks' EGA to 30 days of age is 24 hours. Apnea testing must be performed with each examination, and the $PaCO_2$ must rise to >60 mm Hg and 20 mm Hg above the baseline $PaCO_2$ to document apnea.

Two neurologic examinations and apnea tests separated by an observation period are required to establish the diagnosis of neurologic death in the United States. The duration of observation between examinations is based on age. Ancillary studies are not mandatory to make a determination of neurologic death. The physician caring for the child will determine the need for ancillary studies based on history and the ability to complete the clinical examination and apnea testing. If clinical examination and apnea testing cannot be safely completed, an ancillary study should be used to assist with determination of death.

3. A 2-year-old child has sustained a severe closed head injury. His neurologic examination has deteriorated, and formal brain death testing is being considered. Which of the following is appropriate for the continued care of this patient and the family?
   A. Allow the organ procurement coordinator to assume care and manage this patient to prevent deterioration of the donor.
   B. Provide support for the family during end-of-life care.
   C. Refer the family to the organ procurement organization (OPO) when the parents request information about organ donation.
   D. Seek the family's consent for organ donation after cardiocirculatory determination of death.

   Preferred response: B

Rationale

Continued support for the family during end-of-life care through the donation process is an important aspect of caring for patients in the intensive care unit (ICU). Early referral to the OPO is stressed to coordinate a team approach to donation during discussions with the family. The OPO coordinator will typically work with the ICU team in managing the donor after death has been declared. Evaluation of organs will occur at this time, not prior to death. Seeking consent after cardiocirculatory determination of death is an option but only after discussions regarding withdrawal of care have occurred. Waiting until these discussions have occurred is essential to avoid the perceived ethical conflict that the ICU team is allowing the patient to die so as to recover organs.

4. Evaluation of a 3-year-old child for brain death is being considered. To determine brain death in this child, which of the following is most accurate?
   A. A longer period of observation in this young child is required because of legal issues.
   B. An ancillary study is required to make the diagnosis of brain death in children.
   C. Ancillary studies such as electroencephalogram, radionuclide cerebral blood flow study, and computed tomography angiography are used in children.
   D. A thorough neurologic examination and apnea test are required to make the diagnosis of brain death.

   Preferred response: D

Rationale

In a child older than 1 year, brain death is a clinical diagnosis and does not require an ancillary study unless the examination and apnea test cannot be completed. A thorough neurologic examination and apnea test that is repeated after a specified observation period is required to determine brain death based on clinical criteria. A longer observation period is currently recommended in infants younger than 30 days and for children younger than 1 year. For children older than 1 year, an observation period of 12 hours is recommended. Ancillary studies such as an electroencephalogram and cerebral blood flow study can be used to assist with the diagnosis of brain death. Computed tomography angiography has not been validated in children and cannot be relied on as a diagnostic ancillary test to determine brain death in children. The apnea test must achieve a PCO_2 of ≥60 mm Hg to be consistent with brain death.

Chapter 18: Pediatric Transport: Shifting the Paradigm to Improve Patient Outcome

---

1. According to the Emergency Medical Treatment and Labor Act (EMTALA) established by the COBRA legislation, an appropriate transfer criterion includes which of the following?
   A. The referring hospital must provide care and stabilization within its ability.
   B. The referring physician certifies that the medical benefits expected from the transfer outweigh the risks.
   C. The referring physician consents to transfer after being informed of the risks of transfer.
   D. The receiving facility must have available space and qualified personnel and agree to accept the transfer.

   Preferred response: B

Rationale

EMTALA delineates rules for interfacility transfer. Appropriate transfers must meet the following criteria: (1) the transferring hospital must provide care and stabilization within its ability; (2) the referring physician certifies that the medical benefits expected from the transfer outweigh the risks; (3) the patient consents to transfer after being informed of the risks of transfer; (4) the receiving facility must have available space and qualified personnel and agree to accept the transfer; (5) copies of medical records and imaging studies should accompany the patient; and (6) the interfacility transport must be made by qualified personnel with the necessary equipment.

2. Which of the following characterizes a typical skilled interfacility pediatric transport team in comparison to care providers at a referring hospital?
   A. Administration of drugs not typically available at nontertiary centers
   B. Aggressive, early institution of simple therapies
   C. Availability of superior airway and breathing support modalities
   D. Superior diagnostic capabilities
   Preferred response: B

Rationale

For most pediatric critical illnesses, definitive care, ideally beginning with a skilled interfacility transport team, does not involve miracle drugs or technologies but rather the early, aggressive administration of simple therapies. Therapy that includes timely initiation of resuscitation fluids, early administration of inotropes (frequently via peripheral intravenous or intraosseous catheters), and early antibiotic therapy can improve outcomes.

Chapter 19: Pediatric Vascular Access and Centeses

---

1. What may reduce the risk of catheter-related bloodstream infection?
   A. Antibiotic impregnated catheters
   B. Applying antibiotic ointment to the site twice daily
   C. Changing the site weekly
   D. Exchange over a guidewire every 10 days
   Preferred response: A

Rationale

The risk of bloodstream infection is significantly increased by the presence of a central venous catheter. The increased risk is true for all catheter locations and increases with the total number of catheter days. Routinely changing uninfected catheters over a guidewire or to a different anatomic site does not change the risk.

Coagulase-negative staphylococci, *Enterococcus* species, *Staphylococcus aureus*, *Enterobacter* species, and *Candida* species account for the majority of infections. The risk of infection is decreased by use of antibiotic-impregnated catheters, full barrier precautions at the time of placement, and careful aseptic technique when the line is accessed.

2. Which of the following suggests spontaneous bacterial peritonitis when evaluating fluid obtained from a paracentesis?

   A. Ascitic fluid glucose 22 mg/dL with serum glucose 110 mg/dL

   B. 123 neutrophils/hpf

   C. Multiple organisms in the culture

   D. Total protein 2.2 g/dL

   Preferred response: D

Rationale

Condition	Clinical Characteristics	Laboratory Findings
Spontaneous bacterial peritonitis	Cloudy or turbid Gram stain positive <10%, cultures may be negative, single organism	Neutrophils >250/mm^3 Total protein <1 g/dL LDH and glucose similar to serum

3. Initial management of limb ischemia after arterial catheterization should include which of the following?

   A. Aspirin and local application of nitroglycerin paste

   B. Catheter removal and systemic heparin anticoagulation

   C. Local infusion of alteplase

   D. Thrombectomy within 4 hours

   Preferred response: B

Rationale

Limb ischemia that develops after arterial catheterization first requires immediate catheter removal. If ischemia does not rapidly resolve and no contraindications to anticoagulation exist, heparinization should be considered. In larger vessels, thrombectomy or local infusion of thrombolytic agents such as alteplase may be considered in consultation with vascular surgeons and interventional radiologists.

4. During an ultrasound-guided pericardiocentesis, saline microbubble contrast (saline solution in a syringe that has been agitated) injected through the introducer needle demonstrates the appearance of contrast in the left ventricle. What is the most appropriate next step?

   A. Alerting a cardiovascular operative team for emergency open pericardiotomy

   B. Catheter placement, followed by high-resolution computed tomography coronary arteriography

   C. Insertion of the guidewire

   D. Removal of the needle

   Preferred response: D

Rationale

Several techniques can help to determine if blood obtained during pericardiocentesis is of cardiac or pericardial origin. One technique involves injection of small amounts of saline microbubble contrast (saline solution in a syringe that has been agitated) through the introducer needle while imaging with echocardiography. If contrast bubbles are seen in the heart, then the tip of the needle is intracardiac and should be removed. If bubbles appear in the pericardial sac, then the needle is appropriately placed in the pericardium.

Chapter 20: Emerging Role of Ultrasonography in the Pediatric Intensive Care Unit

---

1. Which of the following statements is true regarding ultrasound guidance by intensivists for vascular access in children?
   A. It is not useful for the placement of umbilical arterial or venous catheters.
   B. It should be performed using active (dynamic) ultrasound guidance, which is superior to physically marking the vessel location preprocedure (static guidance).
   C. It should be performed with a transverse visualization of the vessel, as this is demonstrably superior to needle insertion in the longitudinal plane.
   D. It sufficiently increases safety in multiple studies of femoral and subclavian central venous catheter insertion to be considered the standard of care.
   Preferred response: B

Rationale

Placement of central venous catheters using active ultrasound guidance has been demonstrated to be superior to marking position prior to the procedure. Generalizable studies that demonstrate a significant safety benefit for subclavian vein central venous cannulation under ultrasound in children remain lacking. Advantages of ultrasound use for arterial catheter and umbilical vein catheter placement have been described. There have not been sufficient studies to determine whether transverse or longitudinal guidance approaches for vascular access are advantageous.

2. Which of the following statements is true regarding cardiac ultrasonography by intensivists in children?
   A. It demonstrates good concordance with studies performed and interpreted by expert echocardiographers.
   B. It is useful in cardiac arrest to determine the likelihood of failed return of spontaneous circulation (ROSC) if the heart is not moving.
   C. It is not affected by high intraabdominal pressure.

D. When used for determining intravascular volume status, identical criteria for IVC measurement should be used for mechanically ventilated and spontaneously breathing patients.

Preferred response: A

Rationale

Cardiac ultrasonography by pediatric intensivists and emergency medicine physicians has demonstrated good concordance in terms of both interpretation and image acquisition with ICU ultrasound equipment. Though adult cardiac arrest studies have demonstrated cardiac standstill may predict failure to achieve ROSC, recovery of cardiac function in children on ECMO initiated during CPR has also been described. Increased intrathoracic pressure with mechanical ventilation affects the measurement of the inferior vena cava (IVC) for volume status assessment as well. Accordingly, heart position is also affected by elevated intrathoracic or intraabdominal pressures due to position of the diaphragm and lungs in these clinical scenarios.

3. What is true regarding pulmonary ultrasound in critically ill children?

A. It demonstrates reduced visibility of lung parenchyma and pulmonary vascular structures as consolidation progresses.

B. It is affected by changes in body composition, development, and size throughout the growth of a child.

C. It is prone to artifactual findings, which should be ignored during interpretation of the image.

D. It should be performed with a phased array transducer.

Preferred response: B

Rationale

The appearance of the lung changes throughout pediatric development as infant body water decreases and bones ossify. Early in life, intrathoracic structures may be more visible because of less impedance from lung and bony structures. Through late childhood into adolescence, ongoing growth affects available windows and the depth of visualization in patients. A phased array transducer can visualize areas within the thorax and the pleural line; however this is not optimal for visualizing pleural sliding because the field of view with this type of sector transducer is narrow near the skin. Artifactual pulmonary ultrasound findings, such as B- and Z-lines, have been described as useful for assessing pediatric pulmonary pathology and should be incorporated into the assessment. Consolidation of lung parenchyma increases visualization of structures due to less interference from air as it is excluded from the tissue. B-lines are not apparent in pneumothorax due to separation of the visceral pleura from the chest wall.

Chapter 21: Pediatric Critical Care in Resource-Poor Settings

1. Which one of the following statements is true?
   A. Children with diarrhea and malnutrition may have septicemia and should be treated with penicillin (or ampicillin) and gentamicin even if they are afebrile.
   B. Children with diarrhea and malnutrition have large deficits of albumin, sodium, and water and should be given 5% albumin in saline solution at 10 mL/kg/h for the first 6 hours.
   C. Hypernatremic dehydration is dangerous, and the serum sodium level should be reduced by at least 2 mmol/L every hour using 0.2% saline solution in 5% dextrose.
   D. Hypovolemia caused by acute diarrhea in a malnourished patient should be treated with 5% albumin, if available, rather than saline solution to reduce third-space fluid loss.

   Preferred response: A

Rationale

Dehydration caused by acute diarrhea should be treated with crystalloid rather than colloid (response B). Administration of sodium and albumin may cause heart failure in persons with malnutrition (response D). The serum sodium level should fall no faster than 0.5 mmol/L/h in persons with hypernatremia (response C).

2. What are the three major causes of death in children up to 5 years of age globally?
   A. Neonatal diseases, pneumonia, and diarrhea
   B. Pneumonia, diarrhea, HIV/AIDS
   C. Pneumonia, neonatal diseases, injuries
   D. HIV/AIDS, malaria, malnutrition

   Preferred Response: A

Rationale

While substantial gains have been made in mortality rates of children under 5 years of age, 6.3 million children died within their first year of life in 2013, of which 52% were secondary to infectious causes. Neonatal deaths are contributing to 44% of the annual under-5 deaths per year, followed by pneumonia, diarrheal diseases, and malaria. Pneumonia caused 935 million, diarrhea 578 million, and malaria 456 million deaths in 2013. Other important causes of global under-5-mortality are injuries, which contributed to 0·324 million deaths. Thus, infectious diseases remain the leading cause for child mortality.

3. Basic critical care interventions can be successfully implemented in low- to middle-income countries (LMIC) and lives saved even without presence of an intensive care unit. An example for a successful basic critical care intervention is the following:
   A. Establishment of centers of excellence where critical care technologies and education can be developed as a country increases its standards of care
   B. Implementation of explicit patient exclusion criteria for offering critical care
   C. Introduction of intubation and mechanical ventilation guidelines at district

hospitals

D. Training of village health workers in basic resuscitation and treatment

Preferred Response: D

Rationale

Critically-ill children in LMIC can benefit from timely care even without an ICU. There are increasing numbers of examples of innovative and successful basic critical care interventions in these settings. These include the training of villagers in basic first aid and resuscitation; provision of low-cost simplified antimicrobial regimens and rapid diagnostic tests to rural healthcare workers, day clinics, and homes; quality improvement of district hospital services; reorganization of emergency services at referral hospitals; provision of oxygen therapy for hypoxemic children with pneumonia in district clinics; and home-based treatment applied in a variety of settings that all have proven to be effective and beneficial to critically ill children. Great gains have been made in treating pneumonia by the introduction of oxygen concentrators, oximetry monitoring, and supplemental oxygen administration in Papua New Guinea, interventions that decreased pediatric pneumonia case fatality by 35% at very low cost.

Establishing centers of excellence where critical care technologies can be nurtured so that as a country develops and increases its standards of care can be a viable approach toward building a critical system in some LMIC . This would, however, not be considered as "basic" critical care intervention. Such centers can harbor the skilled personnel within a country who can serve as the catalyst in expanding high-quality care as economic resources increase and mortality gains are realized. The types of ICU medical devices in these settings require careful consideration in terms of initial battery life, ongoing biomedical support, durability, initial cost, and cost of consumables. Development of intensive care in LMIC requires careful resource allocation with predefined patient inclusion and exclusion criteria. Intubation and mechanical ventilation are frequently reserved for tertiary care or private hospitals in LMIC, require an ICU, and are not available for the majority of the population in these settings.

Chapter 22: Educating the Intensivist

---

1. One of the first-year fellows in your critical care program has an overall 25% correct score on his in-training examination. The national statistics for first-year fellows is 78%. His performance in several specialty content areas of respiratory and cardiovascular issues is particularly poor. In addition, evaluation by faculty members and senior fellows indicates that he never speaks up and has difficulty assessing patients, as well as arriving at a diagnosis and formulating an appropriate treatment plan. Of note, his evaluations as a pediatric resident were above average, but he failed his general pediatrics certifying examination. After you ascertain that he does not have personal or family issues that have undue influence on his performance, you implement a remediation plan. Which of the following will likely provide the most benefit in remediation?

A. Assign reading that includes a pediatric critical care textbook and review

articles pertinent to pediatric critical care.

B. Have him complete 10 board review questions each week.

C. Provide one-on-one, twice-weekly didactic lectures from faculty.

D. Provide weekly case-based scenarios for one-on-one discussions.

Preferred response: D

Rationale

Adult learning is different than childhood learning, primarily because adults have greater depth and breadth of experiences and knowledge to build on when they encounter new experiences. They learn best when they are active participants in the learning process. Assigned reading is important to the acquisition of new information and should not be overlooked. However, knowledge retention is unpredictable, and the fellow described in the scenario likely needs something that is more concrete. Although didactic lectures are still considered a critical component of teaching, studies show that learners do not benefit as much from this activity. Practicing test taking by answering board review questions may be of benefit, but only after the learner has developed actual knowledge of concepts that allows him to choose the right answer, rather than memorization of facts. Team-based simulation exercises, especially when coupled with debriefing sessions, are important for functioning in the critical care environment, and although this is a critical component of education in the ICU, it is probably not the ideal scenario to identify the deficiencies of an individual fellow who may not speak up during discussions. Case-based discussions can be used to effectively address curricular elements. This method of education provides the learner with clinical situations that draw on one's knowledge and experience. In addition, one-on-one discussions of case-based scenarios provide the opportunity to identify deficiencies in knowledge and decision making at an individual level. Once these are identified, specific modalities that influence experiential learning (simulation, more complex case-based discussions, focused reading assignments, and practice tests) can be implemented to improve those deficiencies.

2. There are frequent reports from the nursing staff that one of the fellows at the end of her second year of training continues to ignore aseptic techniques when inserting central venous catheters. Several central line–associated bloodstream infections have been observed in patients whose central venous catheters were inserted by this fellow. Which of the following is likely the most effective way to improve this fellow's practice?

A. Ensure that a faculty member supervises all of her procedures.

B. Have her watch a web-based video on central venous catheter insertion.

C. Have her participate in team-based retraining using simulation.

D. Have someone else prepare the patients for the procedure.

Preferred response: C

Rationale

There are a number of web-based videos and podcasts that provide instruction on

central venous catheter insertion and other ICU-related procedures. Although these are useful educational venues and should be used to introduce critical care fellows to procedures at orientation and beyond, having this particular fellow go through this activity will not identify what her deficiencies are and therefore will not point out those deficiencies for focused improvement. Reading a chapter about procedures is likely to be even less helpful. Team-based retraining using simulation for central venous catheter maintenance care has been shown to result in fewer central line–associated infections. Further, recording of a simulation session followed by debriefing allows identification of team member deficiencies and provides the opportunity for constructive feedback and subsequent practice improvement. Having someone else prepare the patients for the procedure is not an effective way of teaching, as the individual will never learn how to improve her own practice. Although the fellow might initially need direct faculty supervision until her technique improves, it is important to remember that learners need graded supervision to allow them to achieve independent practice.

3. A first-year fellow in critical care medicine has scored 2 standard deviations below the national mean on his subspecialty in-training examination. The evaluations from his clinical rotations indicate that he is disorganized, has superficial knowledge of basic pathophysiology, does not pay attention to details, and seldom reads. Of the following, which method will most likely improve his in-training scores?

   A. Assigned reading with monthly testing

   B. Daily didactic lectures

   C. Intensive case-based discussions

   D. Yearly attendance at a national board review course

   Preferred response: C

Rationale

Case-based discussions are generally considered to be an effective way of teaching and learning. Presentation of a case scenario (whether real or put together to illustrate a point) allows review of a patient's clinical course as it evolves, thus providing an opportunity for the instructor to emphasize key points with a discussion of the presenting signs and symptoms, differential diagnosis, and management. The learner has a chance to view the case from the eyes of someone with experience and can improve his or her management skills. It has been shown that this type of discussion provides a focused approach, and the learner better remembers the teaching points.

Although didactic lectures certainly serve a purpose and are important in the education of fellows, the learner is least likely to retain a lot of knowledge from this method of teaching. This is due to multiple factors that include short attention span, sleepiness, and distractions.

Attendance at a board review course may help in recall and preparation for an examination, but it does not provide details of pathophysiology and other facts key to understanding disease and treatment.

Assigned reading with monthly testing may help the program director or faculty members to determine whether the fellow is reading the assignments; improvements

on monthly testing may help determine that his knowledge base is improving. However, repeated testing does not provide information regarding the improvement of a trainee in terms of organizational skills, understanding of disease process, and the ability to apply knowledge in patient assessment and management and achievement of competence.

4. As the newly appointed director for the critical care medicine fellowship program at your institution, one of your duties is to develop an evaluation system for the six competencies. Of the following methods, which will likely provide the most accurate information regarding the patient care skills of the fellows?

   A. Direct observation

   B. Evaluation by nursing staff

   C. In-training examination scores

   D. Quality of progress notes

   Preferred response: A

Rationale

Evaluating trainees is an ongoing process intended to identify areas of strength and weakness and provide insight into techniques for personal and professional development. The ultimate goal is to develop competence, defined as the "habitual and judicious use of communication, knowledge, technical skill, clinical reasoning, emotions, values, and reflection in daily practice." This requires establishing foundational skills in knowledge, practice, and maturity and supporting the trainee in learning to apply these to disparate situations. This is the essence of formative evaluation; it provides not just an assessment of performance at a particular point in time, but a process to attain proficiency in all aspects of care.

Evaluations by nursing staff are an important component in the behaviors of the trainee as a member of a health care team, but they reflect only one aspect of performance. In-training examination scores may reflect medical knowledge, but not how it is applied to evolving clinical situations. Progress notes may reflect the thought processes of the clinician, but they do not reflect demeanor and performance at the bedside and are often focused on providing only the essential medical information for hand-offs, billing, or other purposes. Observation of real-life encounters, on the other hand, provides a rich environment by which one can evaluate the trainee's performance as part of the health care team, his or her ability to apply knowledge and to modify interventions by clinical response, and relationships with patients and families. Additional skills of time management, judgment, and reasoning can also be observed.

Chapter 23: Lifelong Learning

1. You are planning to teach a group of critical care fellows how to manage a patient with acute respiratory distress syndrome. Which of the following instructional techniques takes best advantage of the qualities of the adult learner?

   A. Attending a webinar about ventilation strategies followed by a short quiz

B. Engaging in a detailed review of real patient cases followed by discussion of ventilation strategies

C. Attending a lecture with a PowerPoint presentation followed by a quiz

D. Reading a research article on ARDS and then discussing the merits of the study

Preferred response: B

Rationale

Adult learners thrive with active, engaged learning environments. Although all options have the potential for active, engaged learning, response B, review of real patient cases followed by discussion of care strategy, is an example of problem-based learning and requires active engagement by the learners. It is also clearly related to their experience.

2. Which of the following is an example of an entrustable professional activity (EPA)?

A. Identifies subtle or unusual physical exam findings

B. Recognizes a patient requiring urgent or emergent care and initiates evaluation and management

C. Routinely provides vital signs and other laboratory data on rounds

D. Shows self-awareness of one's own knowledge, skill, and emotional limitations that leads to appropriate help-seeking behaviors

Preferred response: B

Rationale

Domains of competence refer to the six groups of physician subcompetencies defined by ACGME, including medical knowledge, patient care, practice-based learning and improvement, interpersonal and communication skills, professionalism, and systems-based practice. Milestones are the developmental levels of knowledge, skills, and attitudes for each subcompetency and describe the progression of a physician's ability. Entrustable professional activities (EPAs) are tasks or responsibilities that trainees are entrusted to perform unsupervised once they have attained sufficient competency. EPAs have been developed with patient safety in mind, but they also provide a framework for curricular development and lifelong progression of learning. Response B, "recognizes a patient requiring urgent or emergent care and initiates evaluation and management," is a discrete, concrete skill that can be observed and entrusted.

Chapter 24: Public Health Emergencies and Emergency Mass Critical Care

---

1. When a very large, sudden-impact public health emergency (PHE) is announced, which are appropriate actions for intensive care unit (ICU) staff?

A. Prepare for essential mass critical care interventions, including invasive hemodynamic monitoring, early renal replacement therapy, and extracorporeal membrane oxygenation.

B. Staff already in the hospital report to their normally assigned work area.

C. Staff coming in from home report to the emergency department.

D. Supplemental providers may be assigned temporarily to work in a field outside their normal professional practice after just-in-time training, without a credentialing process.

Preferred response: B

Rationale

When a sudden-impact PHE is announced, PICU clinical leaders must immediately focus attention on the safety of patients and staff. The hospital's Hospital Emergency Incident Command System (HEICS) is activated. Normal operations continue until other instructions are received. Staff who are already in the hospital report to their normal assigned work area, notifying their supervisor of their arrival. PICU clinical leaders review the hospital disaster plan, including job action sheets, and discuss pertinent aspects with the staff. When possible, the PICU clinical leaders will be informed about the type, number, and arrival time of anticipated patients. However, such information is often unavailable and inaccurate. Scheduled admissions are reviewed for potential cancellation. Patients in the PICU are evaluated for transfer to a lower level of care or discharge.

Based on the initial assessment, ICU leaders need to determine the number of additional patients who could be accommodated with available staff, equipment, supplies, and space to provide normal standards of care. Additional needs for staff, equipment, and supplies should be communicated through appropriate channels in the HEICS. Additional staff is called in when HEICS instructs the staff who are present to do so. HEICS may reassign staff already in the hospital. Staff responding from outside should report to a labor pool area for assignment. Areas designated for expansion of services and overflow are prepared when instructed by HEICS.

2. In a large public health emergency (PHE) that overwhelms ICU resources despite the implementation of the mass critical care approach, rationing would involve withholding care from those with very high mortality risk in order to reallocate those resources to large numbers likely to benefit from simple interventions. Which authority permits rationing?

A. Hospital disaster plans.

B. Hospital Emergency Incident Command System.

C. National Response Framework.

D. Public health emergency powers are defined on a state-by-state basis, but the authority to ration care is ambiguous in most jurisdictions.

Preferred response: D

Rationale

If a PHE overwhelms resources despite mass critical care approaches, rationing

might be considered. Rationing might occur on a first-come first-served basis or by selecting patients most likely to survive as a result of brief life-saving interventions. Such criteria have been suggested for selecting adults for mass critical care when needs exceed resources. Proposed eligibility criteria include absence of severe chronic conditions, predicted mortality not exceeding an arbitrary upper limit, and improving clinical status on periodic reevaluations. At the present time, there is no evidence, consensus of opinion, or law to support the concept of rationing, much less a particular rationing procedure. For PHE rationing to be a feasible option, public and professional consensus is a necessary foundation. Only then could states create a legal basis and liability protections. Better evidence is needed to formulate eligibility criteria and operational plans for PHE rationing.

3. Which of the following resource-intensive interventions may be delayed or forgone in a mass critical care situation in an attempt to maximize the number of survivors?

   A. Inotropic agents

   B. Mechanical ventilation

   C. Renal replacement therapy

   D. Sedation and analgesia

   Preferred Response: C

Rationale

In mass emergency situations, population-based goals will attempt to maximize the number of survivors by providing immediate lifesaving interventions to all persons who are likely to benefit from them, while delaying or forgoing other interventions. This represents a change from usual standards of care to crisis standards of car, and should only be implemented if other approaches are inadequate. Every effort must be made to guarantee the essential critical care interventions: mechanical ventilation, fluid resuscitation, vasopressors, antibiotics and antidotes, and sedation and analgesia. Interventions that may have to be delayed include invasive hemodynamic monitoring, intracranial pressure monitoring, renal replacement therapy, extracorporeal life support, parenteral nutrition, and frequent recording of fluid balance and vital signs. Clinical decision making may have to be based more often on clinical judgment and less often on laboratory and imaging studies.

Chapter 25: Structure and Function of the Heart

---

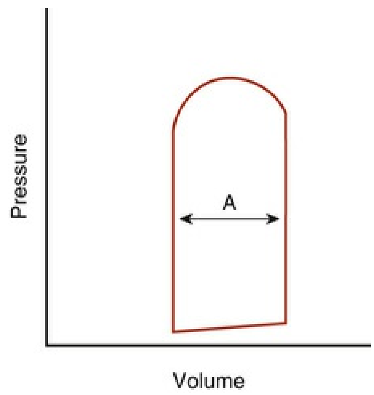
1. What does the segment "A" denote in the pressure-volume loop for a cardiac cycle depicted in Fig. Q25.1?

   A. Ejection fraction

   B. End-diastolic pressure

   C. Ejection time

   D. Stroke volume



Preferred response: D

Rationale

The figure depicts the pressure-volume relationship for a single cardiac cycle. During diastolic filling, volume increases and diastolic pressure rises slightly because of the increase in passive tension. At the end of diastole, isovolumic systole occurs, and ventricular pressure rises with no change in volume. When ventricular pressure exceeds aortic pressure, the aortic valve opens, blood is ejected, and ventricular volume decreases. Ejection ends, and pressure falls to diastolic levels as isovolumic relaxation occurs. The pressure and volume reached at the end of systole are those that would have been attained by the isolated ventricle at that same end-systolic volume. In other words, at a given volume, no higher pressure can be generated. The decrease in volume during ejection is the stroke volume, which, divided by the end-diastolic volume, gives the ejection fraction; normally, ejection fraction is greater than 65%.

2. What is the main difference in the fetal/neonatal myocardium compared with mature adult myocardium?
   A. Complete coupling of β-adrenoreceptors to G proteins
   B. More β-adrenoreceptors
   C. More contractile components
   D. Sparse, disorganized, and immature T tubule and sarcoplasmic reticular system
   Preferred response: D

Rationale

The fetal/neonatal myocardium contains fewer β-adrenoreceptors and fewer contractile components when compared to the adult myocardium. There is incomplete uncoupling of β-adrenoreceptors to G proteins in the fetal/neonatal myocardium as well. The T tubule and sarcoplasmic reticular system of the fetal/neonatal myocardium are sparse and disorganized.

3. In what situation would the left ventricular (LV) pressure-volume relationship in a previously healthy 12-year-old be expected to change from loop abcd to loop a′b′c′d′ in Fig. Q25.3A?
   A. Blood transfusion

B. Hemorrhage

C. Myocardial contusion

D. Use of low-dose epinephrine

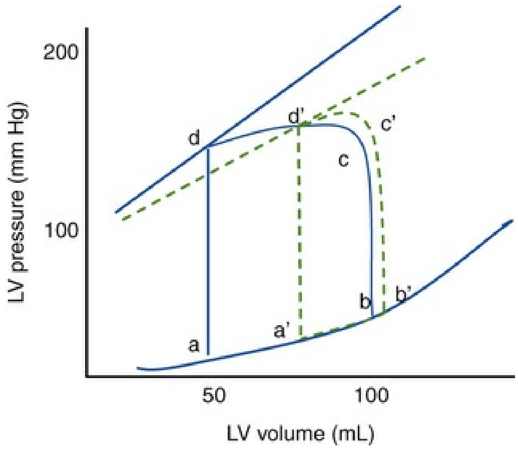


FIG. Q25.3A Ventricular pressure-volume curves.

Preferred response: C

Rationale

Loop abcd represents the pressure-volume relationship in an intact heart. Contraction begins at the end-diastolic pressure and volume of point a. Line ab represents isovolumetric contraction. At point b, the aortic valve opens, as left ventricular (LV) pressure exceeds that in the aorta. Ejection begins at point b and ends at point c. At this point, the aortic pressure is equal to the maximal force produced by the ventricular wall for that specific end-systolic fiber length. Isovolumetric relaxation starts at point c and the aortic valve closes. The ventricular pressure drops (line cd). The mitral valve will open when LV pressure falls below left atrial pressure and blood will flow into the LV.

The difference between lines ab and cd is the stroke volume. Point a represents preload and point b represents afterload.

Loop a′b′c'd′ reflects a decrease in contractility, which could be the result of myocardial contusion. There is a decrease in stroke volume despite a larger end-diastolic volume at a similar level of LV pressure.

Afterload reduction and increase in inotropy (low-dose epinephrine or milrinone) would shift the PV curve to the left and upward.

A blood transfusion increases preload, resulting in an increase in stroke volume (Fig. Q25.3B, loop 2). The contractility has not changed (both end-systolic points are on the same line).

4. At this same level of contractility, what strategies would restore the stroke volume for the patient with myocardial contusion and decreased contractility to his baseline?

   A. Increase in preload and inotropic support

   B. Increase in preload and vasoconstrictor therapy

   C. Increase in preload and vasodilator therapy

   D. Use of diuretics and inotropic support

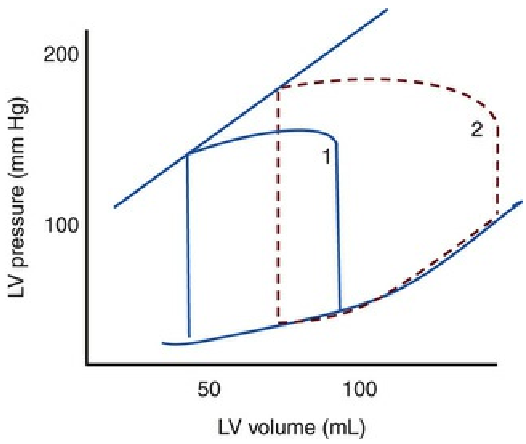

FIG. Q25.3B Ventricular pressure-volume curves.

Preferred response: C

Rationale

In patients with decreased myocardial contractility such as the child in the vignette, stroke volume can be restored with either an increase in preload (loop 4) or a decrease in afterload (loop 3). (See Fig. Q25.4.)

5. Loop 1 in Fig. Q25.5 represents the pressure-volume loop in an intact heart. What is the correct statement regarding the other loops (2 and 3)?
   A. Loop 2 reflects a decrease in preload, as would occur with diuretics.
   B. Loop 3 reflects a decrease in preload, as would occur with diuretics.
   C. Loop 2 demonstrates the effect of increasing afterload.
   D. Loop 2 demonstrates the effect of decreasing afterload.

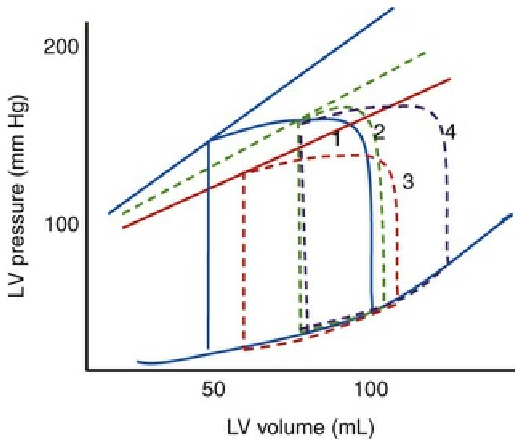

FIG. Q25.4 Ventricular pressure-volume curves.

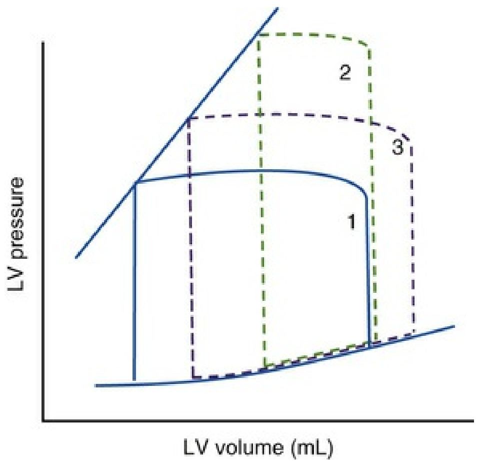

FIG. Q25.5 Ventricular pressure-volume curves.

Preferred response: C

Rationale

The figure represents the response of a normal heart to an increase in afterload. Loop

1 represents the normal physiologic pressure-volume loop. Stroke volume is diminished in loop 2 due to an increase in afterload. Loop 3 represents a compensatory response to the increase in afterload. Contraction begins at a higher end-diastolic volume. The heart ejects the same stroke volume at a higher afterload. Even though the stroke volumes for loops 1 and 3 are the same, the ejection fraction is lower for loop 3, as the end-diastolic volume is increased.

6. Except in young infants, what is the preferential source of energy for myocardial function?

   A. Glucose

   B. Glycogen

   C. Ketones

   D. Long-chain fatty acids

   Preferred response: C

Rationale

In all except young infants, the preferential source of energy for myocardial function comes from the β-oxidation of long-chain fatty acids. After fatty acids enter the cell, they are activated to fatty acid (or acyl) coenzyme A (CoA) compounds by palmitoyl-CoA synthetase, then linked by carnitine palmitoyl transferase I to carnitine to form acylcarnitines, thus releasing CoA. The acylcarnitines cross the mitochondrial membrane, and at the inner surface of the membrane another enzyme, carnitine palmitoyl transferase II, transfers the fatty acids back to CoA. The fatty acids can now undergo β-oxidation with the production of ATP. These enzymes also help transport acylcarnitine esters of CoA out of the mitochondria. These esters are toxic in high concentrations. Fetuses and neonates have decreased activity of carnitine palmitoyl transferase and palmitoyl-CoA synthetase, so glucose, lactate, and short-chain fatty acids are the preferred myocardial energy substrates at this age.

7. Which of the following statements is true concerning endothelins?

   A. Bosentan is an endothelin agonist.

   B. Endothelins act on the ET_A receptor and cause vasodilation.

   C. Endothelins act on the ET_B receptor and cause vasoconstriction.

   D. Endothelins cause either vasoconstriction or vasodilation.

   Preferred response: D

Rationale

The vascular endothelium elaborates the endothelins (ET-1, ET-2, ET-3), a family of compounds that are vasoactive, structurally related peptides. ET-1 is the most potent vasoconstrictor known. It also promotes mitogenesis and stimulates the renin-angiotensin-aldosterone system and the release of vasopressin and atrial natriuretic peptide. These peptides act on one of two receptor subtypes: ET_A and ET_B. ET_A is located mainly on vascular smooth muscle cells and is responsible for mediating vasoconstriction and cell proliferation. ET_B is present predominantly on endothelial

cells and mediates vasorelaxation, as well as ET-1 clearance. Endothelins cause local vasoconstriction or vasodilatation, depending on dose and location in the circulation. Individual endothelins occur in low levels in the plasma, generally below their vasoactive thresholds. This finding suggests they are primarily effective at the local site of release. Even at these levels, however, they may potentiate the effects of other vasoconstrictors such as norepinephrine and serotonin. Endothelin antagonists, such as bosentan, now are being used specifically in the setting of pulmonary arterial hypertension.

8. Which of the following statements is true regarding the regulation of vasomotor tone?
   A. Adenosine causes vasoconstriction.
   B. Hypokalemia causes vasodilation.
   C. Hyperkalemia causes vasodilation.
   D. Neuropeptide Y causes vasodilation.
   Preferred response: C

Rationale

Local metabolic regulation of vasomotor tone provides an ideal homeostatic mechanism whereby metabolic demand can directly influence perfusion. Adenosine, which accumulates locally when tissue metabolism is high and tissue oxygenation is marginal, causes pronounced vasodilatation in the coronary, striated muscle, splanchnic, and cerebral circulations.

Potassium is released from muscle in response to increased work, ischemia, and hypoxia. Hypokalemia causes vasoconstriction. Hyperkalemia, within the physiologic range, causes vasodilatation by stimulating KIr channels.

In all organs, sensory and efferent nerve endings contain nonadrenergic, noncholinergic (NANC) peptides—for example, neuropeptide Y, VIP, calcitonin gene-related peptide (CGRP), and substance P. Neuropeptide Y is colocalized and released with norepinephrine, and VIP is colocalized with acetylcholine and released upon stimulation of vagal nerve endings. Most of these peptides except neuropeptide Y are vasodilatory, and they help modulate blood pressure and regional flows.

Chapter 26: Regional Peripheral Circulation

---

1. The difference between autoregulated and maximal coronary flow is termed *coronary flow reserve.* What does the coronary flow reserve indicate?
   A. Maximal coronary artery vasoconstriction to meet increased demands for oxygen
   B. Maximal cardiac oxygen consumption
   C. Maximal ventricular contraction at any given coronary flow
   D. The amount of myocardial blood flow that can increase at any given pressure in

order to meet increased oxygen demands

Preferred response: D

Rationale

At any given pressure, the difference between autoregulated and maximal flows is termed *coronary flow reserve*. Coronary flow reserve indicates how much extra flow the myocardium can get at a given pressure to meet increased demands for oxygen; if reserve is much reduced, then flow cannot increase sufficiently to meet demands and myocardial ischemia will occur. Coronary flow reserve is normally lower in the subendocardium than in the subepicardium, and decreases in coronary flow reserve are always more profound in the subendocardium than in the subepicardium.

If autoregulated flow is normal but maximal flow is decreased, then coronary flow reserve will be reduced. Coronary flow reserve also can be reduced if maximal flows are normal but autoregulated flows increase.

2. Nitric oxide (NO) is a labile humoral factor produced by nitric oxide synthase from L-arginine in the vascular endothelial cell. Which of the following is true of nitric oxide?

   A. Decreases significantly in the pulmonary vasculature immediately after birth

   B. Is important in basal vascular tone, but less so for dynamic changes in vascular tone

   C. Is increased in response to increases in shear/flow across endothelial cells

   D. Produces vascular smooth muscle cell contraction by increasing the concentration of cGMP via the activation of soluble guanylate cyclase

   Preferred response: C

Rationale

NO is a labile humoral factor produced by NO synthase from L-arginine in the vascular endothelial cell. NO diffuses into the smooth muscle cell and produces vascular relaxation by increasing concentrations of cGMP via the activation of soluble guanylate cyclase. NO is released in response to a variety of factors, including shear stress (flow) and the binding of certain endothelium-dependent vasodilators (such as acetylcholine, adenosine triphosphate [ATP], and bradykinin) to receptors on the endothelial cell. Basal NO release is an important mediator of both resting pulmonary and systemic vascular tone in the fetus, newborn, and adult, as well as a mediator of the fall in pulmonary vascular resistance normally occurring at the time of birth. Dynamic changes in NO release are fundamental to the regulation of all vascular beds.

3. Of the following agents, which has the most potent vasoconstricting properties?

   A. Angiotensin II

   B. Aldosterone

   C. Endothelin-1

   D. Thromboxane A_2

   Preferred response: C

Rationale

Endothelin-1 (ET-1) is produced by vascular endothelial cells. It has complex vasoactive properties, the most striking of which is its sustained hypertensive action. ET-1 is the most potent vasoconstricting agent discovered, with a potency 10 times that of angiotensin II.

Humoral regulators of vascular tone include angiotensin, arginine vasopressin, bradykinin, histamine, and serotonin. Of less importance are thyroxine, aldosterone, and antinatriuretic peptide. Angiotensin plays a special role in the homeostasis of blood pressure and is produced in persons with hemorrhagic or hypovolemic shock. It causes generalized vasoconstriction in both systemic and pulmonary circulations, but locally it stimulates the release of vasodilating prostaglandins in lung and kidney.

Bradykinin is a potent pulmonary and systemic vasodilator released locally by the action of the proteolytic enzymes on kallikrein after tissue injury.

Breakdown of phospholipids within vascular endothelial cells results in production of important byproducts of arachidonic acid, including prostacyclin (PGI_2) and thromboxane (TXA_2). PGI_2 activates adenylate cyclase, resulting in increased cyclic adenosine monophosphate (cAMP) production and subsequent vasodilation, whereas TXA_2 results in vasoconstriction via phospholipase C signaling.

4. Which of the West zones of the lung are effectively perfused in proportion to their height above the left atrium?

A. Zones I and II

B. Zone II only

C. Zones I and III

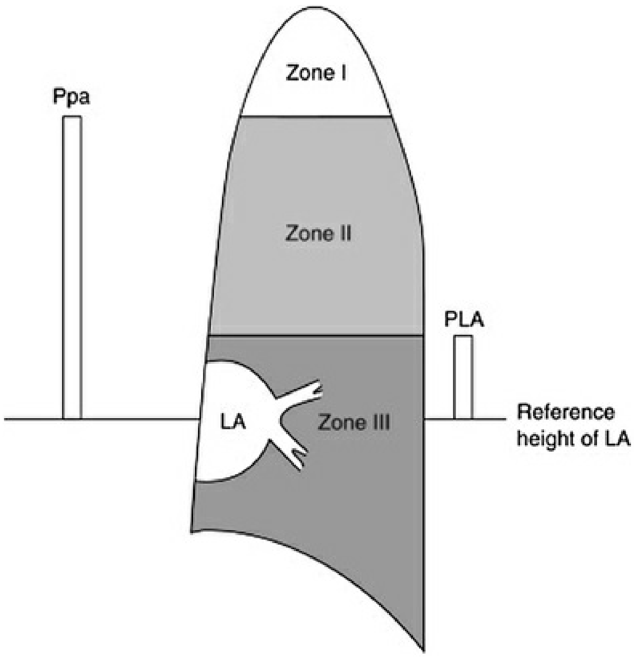
D. Zone III only

Preferred response: B

Rationale

The inflow pressure of the pulmonary circulation is low, thus creating a vertical gradation to the distribution of blood flow in the lung. Hydrostatic pressure must be adjusted for vertical height above the left atrium, both at the inflow and at the outflow of every alveolar capillary unit. For example, given a pulmonary artery mean pressure of 20 cm H_2O (zeroed at the level of the left atrium), an alveolar capillary unit 12 cm above the left atrium faces an inflow pressure of only 8 cm H_2O. A left atrial pressure of 5 cm H_2O generates no opposing outflow pressure to an alveolar capillary unit more than 5 cm above the left atrium. Critical closing pressure of postcapillary vessels therefore sets outflow pressure for a unit 10 cm above the left atrium. If intrinsic vascular resistance were identical throughout the lung, flow at any vertical height would be determined by hydrostatic driving pressure (inflow-outflow) and would be greatest at the base and least at the apex of the lung. This phenomenon partitions the lung into three vertical regions, named West zones. Zone I vessels are higher above the left atrium than pulmonary artery pressure and are not perfused by the pulmonary artery. Zone II vessels lie above the height defined by the

hydrostatic left atrial pressure but below the height of the pulmonary artery pressure. These units are perfused in proportion to the driving pressure across them, which is approximately pulmonary artery pressure less vertical height (or critical closing pressure, whichever is higher). Zone III vessels lie at a vertical height less than outflow pressure. Driving pressure across these units is independent of height because inflow and outflow pressures are comparably influenced by gravity.



5. In which of the following vascular beds do neural stimuli exert little effect on basal blood flow under physiologic conditions?
   A. Cerebral
   B. Coronary
   C. Muscular
   D. Pulmonary
   Preferred response: A

Rationale

In marked contrast to other vascular beds, neural stimuli have relatively little effect on basal cerebral blood flow (CBF). Cerebral vessels display extensive perivascular innervations, especially the sympathetic nerves arising from the superior cervical sympathetic ganglia, but the brain is well protected from circulating catecholamines by the blood-brain barrier. Thus many of the vasoactive agents used in the critical care setting (α- and β-adrenergic agonists) have minimal effects on resting cerebral vascular tone. Mild to moderate electrical stimulation, as well as surgical resection of both the sympathetic and parasympathetic nervous system, does not alter cerebral vascular tone under resting conditions. However, vigorous sympathetic stimulation, as occurs with strenuous exercise or hypertension, does result in vasoconstriction of large- and medium-size cerebral vessels. Thus a neurogenic mechanism may not

mediate cerebral vascular resistance under normal conditions, but it does provide protection at times of stress.

6. Which of the following substrates can the brain use during periods of starvation?
   A. Arginine
   B. Glutamine
   C. Glycogen
   D. Ketones
   Preferred response: D

Rationale

At rest, cerebral blood flow is approximately 50 mL/100 g tissue/min. Cerebral oxygen consumption is surprisingly high, averaging 3.2 mL/100 g tissue/min. Glucose is the primary energy substrate, although ketones can be utilized during periods of starvation. The brain has no functional capacity to store energy and thus is completely dependent on a steady supply of O_2 because up to 92% of its adenosine triphosphate (ATP) production results from the oxidative metabolism of glucose.

7. Which of the following drugs should be used with caution in patients with increased intracranial pressure due to a risk of precipitating herniation?
   A. Esmolol
   B. Lorazepam
   C. Nitroprusside
   D. Pentobarbital
   Preferred response: D

Rationale

Nitroprusside and other nitric oxide donor compounds can dilate cerebral vessels. This process greatly complicates the management of hypertension in patients with increased intracranial pressure. In such patients, nitroprusside may reduce arterial pressure but raise cerebral blood flow and blood volume, thereby causing herniation.

8. Which of the following mediators has been implicated in the vasospasm following subarachnoid hemorrhage?
   A. Adenosine
   B. Carbon dioxide
   C. Cyclic AMP (cAMP)
   D. Endothelin-1 (ET-1)
   Preferred response: D

Rationale

Substance P, acetylcholine, oxytocin, ET-1, adenosine diphosphate, ATP, and prostaglandin cause nitric oxide (NO)-dependent cerebral vasodilation. Impaired NO signaling is important in the pathophysiology of subarachnoid hemorrhage in

which endothelial dysfunction has been well documented, leading to the important clinical problem of vasospasm.

ET-1 is an important mediator of cerebrovascular tone. Both ETA and ETB receptors have been identified in the cerebral vasculature. ET-1 given in high concentrations constricts cerebral vessels, probably via ETA receptor activation. However, ET-1 given in low concentrations relaxes cerebral vessels via endothelial cell ETB receptor activation, a response that is NO dependent. ET-1 has been identified as an important mediator of vasospasm following subarachnoid hemorrhage. ET-1 levels are increased following subarachnoid hemorrhage. In association with the increase in ET-1 levels are increases in ETA receptor levels, smooth muscle cell ETB receptor levels (which mediate vasoconstriction), and endothelin-converting enzyme activity.

Adenosine leads to cerebral vasodilation through an increase in cAMP and increases more than fivefold with hypoxia. Adenosine is critical in CBF autoregulation.

Carbon dioxide plays a critical role in regulation of CBF. A linear increase in CBF is seen with increasing $PaCO_2$, making CO_2 one of the most potent known cerebral vasodilators. Carbon dioxide exerts its effect via reduction in perivascular pH. Arterial H^+ cannot cross the blood-brain barrier, but CO_2 can easily diffuse into the brain. Perivascular acidosis dilates the cerebral vasculature, whereas alkalosis leads to vasoconstriction.

9. In the normal heart, which of the following regions is more prone to ischemia because of low perfusion pressure?

A. Right ventricle subepicardial regions

B. Right ventricle subendocardial regions

C. Left ventricle subepicardial regions

D. Left ventricle subendocardial regions

Preferred response: D

Rationale

Myocardial perfusion over a cardiac cycle is normally approximately the same per gram of tissue in the outer (subepicardial), mid, and inner (subendocardial) layers of the left ventricle, but the dynamics during the cardiac cycle are complicated. At the end of diastole, when the ventricle is relaxed and tissue pressures are probably less than 10 mm Hg in any layer of the left ventricle, pressures in the intramural arteries are probably similar to each other and to aortic pressure. At the beginning of systole, tissue pressure rises to equal intracavitary pressure in the subendocardium but then falls off linearly across the wall to about 10 mm Hg in the subepicardium. These pressures are for an instant added to those inside the vessels because the vessels' walls are not rigid, and as a result, intravascular pressures in subendocardial arteries exceed aortic pressures, but aortic pressures are higher than are pressures in subepicardial arteries. These pressure gradients and the greater shortening of subendocardial versus subepicardial muscle fibers during systole compress the subendocardial vessels and squeeze blood out of them both forward into the coronary sinus and backward toward the epicardium. In fact, narrowing of the subendocardial vessels facilitates thickening and shortening of the myocytes. This

backflow enters the subepicardial arteries to supply their systolic flow. In systole, some forward flow into the orifices of the coronary arteries does indeed occur, but this forward flow does not perfuse the myocardium; it merely fills the extramyocardial arteries. In fact, there is often reverse flow in the epicardial coronary arteries. In early diastole, blood flows first into the subepicardial vessels that have not been compressed, but it takes longer to refill the narrowed subendocardial vessels. Given enough time and perfusing pressure, all the myocardium will be perfused, but if diastole is too short or perfusion pressure is too low, subendocardial ischemia occurs. Right ventricular myocardium, on the other hand, normally is perfused both in systole and in diastole, because of lower tissue pressures.

10.Based on the graph for pressure-flow relations in the left coronary artery during normal flow and maximal vasodilation, which of the following statements is correct?

A. Coronary vascular reserve is independent of perfusion pressure.

B. For normal maximal flow, flow is uncoupled from metabolism.

C. For normal autoregulated flow, flow is uncoupled from metabolism.

D. For normal autoregulated flow, an increase in heart rate will increase maximal flow at any perfusion pressure.

Preferred response: C

Rationale

Coronary vascular resistance has three components: a basal low resistance in the arrested heart with maximally dilated vessels, an added resistance when vessels have tone, and a phasic resistance added whenever the ventricle contracts. In the beating heart with vessels maximally dilated by a pharmacologic dilator, the second of these resistances is absent. Perfusion of the left ventricular myocardium then produces a steep pressure-flow relation that is linear at higher flows but usually curvilinear at low pressures and flows (Fig. Q26.10A). Because the vessels are maximally dilated, flow is uncoupled from metabolism and depends only on driving pressure and resistance. If heart rate is increased, maximal flow at any perfusion pressure decreases because the heart is in a relaxed state for a smaller proportion of each minute.

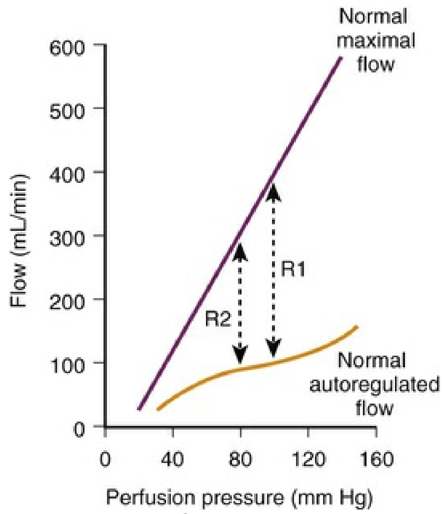


FIG. Q26.10A Normal pressure-flow relations in the left coronary artery during normal autoregulated flow and during maximal vasodilation. Values are appropriate for a left ventricle weighing approximately 100 g. R1, R2, coronary flow reserve measurements at two different coronary perfusing pressures.

If tone is allowed to return to the coronary vessels, then the pressure-flow relationship can be assessed at different perfusion pressures after cannulating the left coronary artery. It is necessary to do this because when cardiac metabolism and blood flow are coupled, increasing aortic blood pressure will increase coronary flow not only by increasing perfusion pressure but also by increasing myocardial oxygen demand. Under normal conditions coronary blood flow is autoregulated, such that if perfusion pressure is raised or lowered from its normal value, there is a range over which almost no change in flow occurs; a rise in pressure has caused vasoconstriction, and a fall in pressure has caused vasodilatation. At perfusion pressures above some upper limit, flow increases, probably because the pressure overcomes the constriction. More important, at pressures below about 40 mm Hg (but varying, as discussed later), flow decreases predominantly in the deep subendocardial muscle (Fig. Q26.10B), indicating that some vessels have reached maximal vasodilatation and can no longer decrease resistance to compensate for the decreased perfusion pressure. In these vessels, flow and pressure are directly related. If this pressure dependency occurs, then a further decrease in perfusion pressure decreases local blood flow below the required amount, or if myocardial oxygen demands increase at the same low perfusion pressure (as will occur if the ventricle becomes dilated), the requisite increase in flow will not occur. These two conditions cause subendocardial ischemia.

At any given pressure, the difference between autoregulated and maximal flows is termed *coronary flow reserve.* (Coronary flow reserve can be measured in units of mL/min but also can be assessed by a dimensionless flow reserve ratio derived by dividing maximal flow by resting flow.) Flow reserve depends on perfusion pressure because of the steepness of the pressure-flow relation in maximally dilated vessels. Coronary flow reserve indicates how much extra flow the myocardium can get at a given pressure to meet increased demands for oxygen; if reserve is much reduced, then flow cannot increase sufficiently to meet demands and myocardial ischemia will occur. What the figure does not show is that coronary flow reserve is normally

lower in the subendocardium than in the subepicardium and that decreases in coronary flow reserve are always more profound in the subendocardium than in the subepicardium.

11. Regarding coronary artery perfusion, a shift from normal autoregulated flow to increased autoregulated flow may be seen in which of the following conditions?
   A. Myocardial ischemia
   B. Coronary spasm
   C. Increased blood viscosity
   D. Carbon monoxide poisoning
   Preferred response: D

Rationale

Coronary flow reserve also can be reduced if maximal flows are normal but autoregulated flows increase (Fig. Q26.11A). Increased myocardial flows above normal values can occur with exercise, tachycardia, anemia, carbon monoxide poisoning, leftward shift of the hemoglobin oxygen dissociation curve (as in infants with a high proportion of fetal hemoglobin), hypoxemia, thyrotoxicosis, acute ventricular dilatation (because of increased wall stress), inotropic stimulation by catecholamines, and acquired ventricular hypertrophy. If autoregulated flow is normal but maximal flow is decreased, as indicated by the decreased slope of the pressure-flow relation during maximal dilatation (Fig. Q26.11B), then coronary flow reserve will be reduced. Such a change can occur with marked tachycardia; a decrease in the number of coronary vessels due to small vessel disease, as in some collagen vascular diseases, especially systemic lupus erythematosus; increased resistance to flow in one or more large coronary vessels because of embolism, thrombosis, atheroma, or spasm; impaired myocardial relaxation due to ischemia; myocardial edema; a marked increase in left ventricular diastolic pressure; marked increase in left ventricular systolic pressure if coronary perfusion pressure is not also increased, as in aortic stenosis or incompetence; and an increase in blood viscosity, most commonly seen with hematocrit levels higher than 65%.

12. Pulmonary embolism and subsequent right ventricular failure develops in a previously normal 17-year-old patient. Which of the following drugs would help restore right ventricular function to normal?
   A. Dobutamine
   B. Esmolol
   C. Milrinone
   D. Norepinephrine

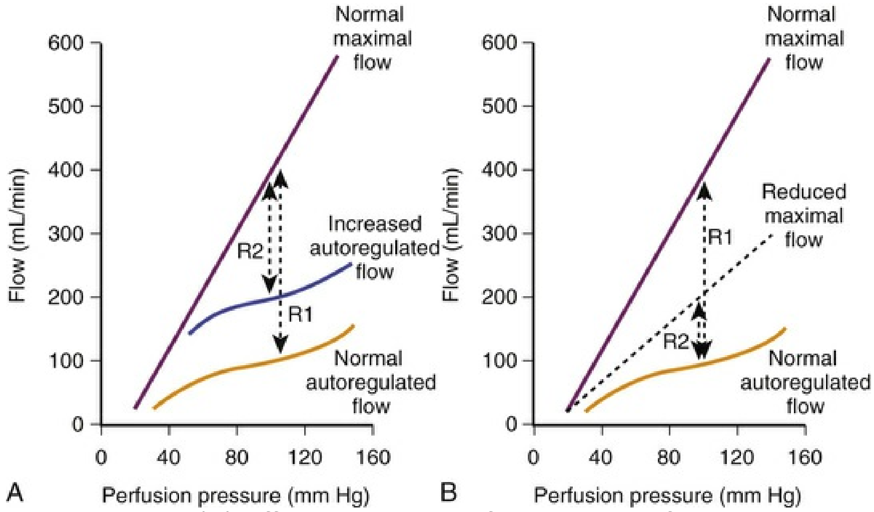

FIG. Q26.11 (A) Effect on coronary flow reserve of an increased autoregulated flow. Reserve is reduced from R1 to R2. (B) Effect on coronary flow reserve of a reduced maximal flow. At the same coronary perfusing pressure, flow reserve is reduced from the normal R1 to R2.

Preferred response: D

Rationale

Right ventricular myocardial blood flow is affected by the low right ventricular systolic pressure and the fact that changes in aortic pressure alter coronary perfusion pressure without altering right ventricular pressure work. If the normal right ventricle is acutely distended—for example, by pulmonary embolism—eventually right ventricular failure occurs. The increased wall stress increases oxygen consumption but the raised systolic pressure reduces coronary flow, so when supply cannot match demand, right ventricular myocardial ischemia occurs. Raising aortic perfusing pressure mechanically or with α-adrenergic agonists increases right ventricular myocardial blood flow, relieves ischemia, and restores right ventricular function to normal. Improved coronary flow is not the only mechanism of this improvement; increased left ventricular afterload moves the ventricular septum toward the right ventricle and improves left ventricular performance.

Chapter 27: Endothelium and Endotheliopathy

1. The endothelium plays an important role in controlling the vascular tone. Which of the following endothelium-derived factors is least likely to cause vasodilation?
   A. Acetylcholine
   B. Endothelin
   C. Endothelium-derived hyperpolarizing factor
   D. Nitric oxide (NO)
   Preferred response: B

Rationale

Endothelin is an endothelium-derived vasoconstrictor. All other choices are endothelium vasodilators. The vasodilatory action of acetylcholine is derived through NO. Both NO and prostacyclin can be used clinically.

2. Binding of thrombin to cell surface thrombomodulin facilitates activation of which of the following?

   A. Antithrombin III

   B. Platelets

   C. Protein C

   D. Protein S

   Preferred response: C

Rationale

Thrombin activity is also modulated by endothelial cell synthesis of thrombomodulin. The binding of thrombin to thrombomodulin facilitates the enzyme's activation of the anticoagulant protein C. Activated protein C (APC) activity is enhanced by cofactor C, also called protein S, which is synthesized by endothelial cells as well as other cells (Fig. Q27.2). APC inhibits factor Va and factor VIIIa.

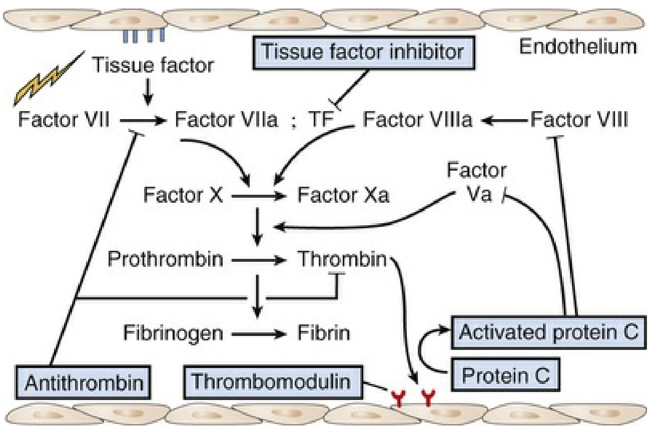

FIG. Q27.2

APC has a variety of antiinflammatory activities. It suppresses inflammatory cytokine during sepsis, inhibits leukocyte adhesion, decreases leukocyte chemotaxis, reduces endothelial cell apoptosis, helps maintain endothelial cell barrier function through activation of the sphingosine-1 phosphate receptor, and minimizes the decrease in blood pressure associated with severe sepsis.

Another interesting effect of APC is its plasminogen activator inhibitor 1 (PAI-1) neutralizing effect. PAI-1 is a glycoprotein that acts as an acute-phase protein during acute inflammation. Its primary role in vivo is the inhibition of both tissue- and urokinase-type plasminogen activators. PAI-1 is the most efficient inhibitor of APC and thrombin in the absence of heparin. PAI-1 competes with thrombomodulin for binding with thrombin, which, in combination with its inhibition of APC, makes it a

strong local procoagulant by a combined action of displacing and inactivating anticoagulant thrombin from thrombomodulin. In this way PAI-1 has important pathophysiologic effects in acute and chronic diseases.

3. Protein C acts by inhibiting the activities of which of the following?
   A. Factors II and V
   B. Factors II and Xa
   C. Factors Va and VIIIa
   D. Factors VIIa and Xa
   Preferred response: C

Rationale

See Fig. Q27.3.

4. Exposure and binding of endothelial tissue factor to which of the following factors initiates the coagulation cascade, resulting in the formation of fibrin?
   A. Factor II
   B. Factor Va
   C. Factor VIIa
   D. Factor VIII

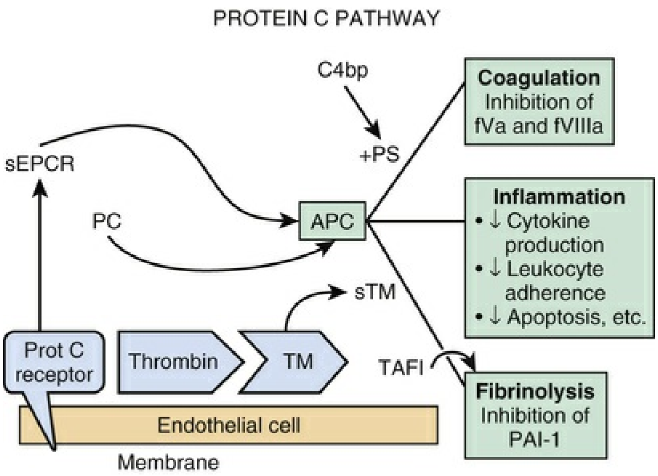

FIG. Q27.3

Preferred response: C

Rationale

The expression and release of tissue factor is the pivotal step in transforming the endothelium from an anticoagulant to a procoagulant surface. Tissue factor accelerates factor VIIa–dependent activation of factors X and IX (Fig. Q27.4). The synthesis of tissue factor is induced by a number of agonists, including thrombin, endotoxin, several cytokines, shear stress, hypoxia, oxidized lipoproteins, and other endothelial insults. Once endothelial cells expressing tissue factor are exposed to plasma, prothrombinase activity is generated and fibrin is formed on the surface of

the cells. Tissue factor also can be found in plasma as a soluble protein. Its role there is not well understood, but it probably plays a role in the initiation of coagulation.

5. Which of the following causes the production of inducible NO synthase (iNOS)?
   A. Bradykinin
   B. Histamine
   C. Insulin
   D. Tumor necrosis factor-α
   Preferred response: D

Rationale

NO is generated from the conversion of L-arginine to NO and L-citrulline by the enzyme nitric oxide synthase (NOS). Two general forms of NOS exist: constitutive and inducible. In the unstimulated state, NO is continuously produced by constitutive NOS (cNOS). The activity of cNOS is modulated by calcium that is released from endoplasmic stores in response to the activation of certain receptors. Substances such as acetylcholine, bradykinin, histamine, insulin, and substance P stimulate NO production through this mechanism. Similarly, shearing forces acting on the endothelium are another important mechanism regulating the release of NO. The inducible form of NOS is not calcium dependent but instead is stimulated by the actions of cytokines (eg, tumor necrosis factor-α and interleukins) or bacterial endotoxins (eg, lipopolysaccharide). Induction of iNOS occurs over several hours and results in NO production that may be more than 1000-fold greater than that produced by cNOS. This mechanism is important in the pathogenesis of inflammation (Fig. Q27.5).

6. Where is NO produced?
   A. Endothelial cell
   B. Neutrophils
   C. Platelets
   D. Red blood cell
   Preferred response: A

Rationale

Furchgott and Zawadzki first postulated the existence of an endothelial relaxing factor in 1980, when they noticed that the presence of endothelium was essential for rabbit aortic rings to relax in response to acetylcholine. Later, it was determined that the biological effects of endothelial relaxing factor are mediated by NO. NO is generated in the endothelial cell from the conversion of L-arginine to NO and L-citrulline by the enzyme NOS.

7. NO acts by which of the following mechanisms?
   A. Binding to cyclic adenosine monophosphate (cAMP)
   B. Binding to cyclic guanosine monophosphate (cGMP)
   C. Binding to adenyl cyclase
   D. Binding to guanylyl cyclase

Preferred response: D

Rationale

Once NO is formed by an endothelial cell, it readily diffuses out of the cell and into adjacent smooth muscle cells, where it binds to and activates the soluble form of guanylyl cyclase, resulting in the production of cGMP from guanosine triphosphate.

8. Prostacyclin acts by which of the following mechanisms?
   A. Binding to cAMP
   B. Binding to cGMP
   C. Binding to guanylyl cyclase
   D. Binding to prostacyclin receptors
   Preferred response: D

Rationale

Prostacyclin is a potent vasodilator that is active in both the pulmonary and systemic circulations. In addition to its vasodilatory effects, prostacyclin also has antithrombotic and antiplatelet activity. Its release may be stimulated by bradykinin and adenine nucleotides. Like NO, it is chemically unstable with a short half-life. However, unlike NO, prostacyclin activity in arterial beds depends on its ability to bind to specific receptors in vascular smooth muscle. Its vasodilator activity is therefore determined by the expression of such receptors. Prostacyclin receptors are coupled to adenylate cyclase to elevate cAMP levels in vascular smooth muscle. The increase in cAMP results in (1) stimulation of adenosine triphosphate–sensitive K^+ channels, resulting in hyperpolarization of the cell membrane and inhibition of the development of contraction, and (2) increased efflux of Ca^{2+} from the smooth muscle cell and inhibition of the contractile machinery.

9. Which of the following statements regarding the interaction between nitric oxide (NO) and prostacyclin is correct?
   A. NO inhibits the action of prostacyclin.
   B. NO and prostacyclin act sequentially to cause vasodilation.
   C. Prostacyclin inhibits the action of NO.
   D. Prostacyclin facilitates the cellular release of NO.
   Preferred response: D

Rationale

Prostacyclin facilitates the release of NO by endothelial cells, and the action of prostacyclin in vascular smooth muscle is potentiated by NO. Interestingly, NO also may potentiate the effects of prostacyclin. The NO-mediated increase in cGMP in smooth muscle cells inhibits a phosphodiesterase that breaks down cAMP, therefore indirectly prolonging the half-life of the second messenger of prostacyclin.

Chapter 28: Principles of Invasive

Monitoring

1. A 7-day-old male with *d*-transposition of the great arteries presents 8 hours after an arterial switch operation with a heart rate of 180 beats per minute and hypotension (mean arterial pressure of 35 mm Hg). He appears to have A-V dissociation on telemetry. What would be the most likely pattern seen on the central venous pressure (CVP) monitor?

   A. Broad, flat *a* waves

   B. Enlarged *a* waves

   C. Fused *c* and *v* waves

   D. Steep abrupt x and y descent

   Preferred response: B

Rationale

Cannon *a* waves are enlarged *a* waves seen when the right atrium is ejecting against a closed tricuspid valve, and they may be seen when atrioventricular discordance occurs (in this case, during an episode of postoperative junctional ectopic tachycardia). They will resolve once the underlying illness is treated. Response C occurs in tricuspid regurgitation, when the backflow of blood out of the right ventricle obliterates the x descent and the *c* wave becomes accentuated. Response D occurs during pericardial constriction or tamponade physiology. Although the patient is tachycardic and hypotensive, there are no other signs, from the stem, that the patient has this physiology. Response A, or loss of *a* wave, occurs during atrial fibrillation because loss of atrial contraction results in missing the *a* wave.

2. An otherwise healthy infant has a peripheral arterial line placed in his dorsalis pedis for monitoring during an elective surgery. What discrepancy is likely to be found between a cuff blood pressure on the arm and the readings assessed from the arterial line?

   A. The mean arterial pressure (MAP) measurements will be widely different.

   B. The systolic blood pressure (SBP) measurement will be lower on the intraarterial measurement.

   C. The diastolic blood pressure (DBP) measurement will be lower on the intraarterial measurement.

   D. The MAPs will be the same, but the SBP on the cuff pressure will be higher.

   Preferred response: C

Rationale

This is referred to as *distal pulse amplification* and occurs due to the nature of the vascular tree; the systolic blood pressure increases, and diastolic blood pressure decreases as you move peripherally, with a more exaggerated pulse pressure. The MAPs remain the same between the peripheral and central sites. Pressure waveform measurements from different sites of the arterial tree have varying morphologies

depending on the properties of the vascular bed. The changes that occur as you move peripherally have to do with alterations in impedance and harmonic resonance.

3. A 10-year-old child has been admitted to the intensive care unit (ICU) in shock. The child is endotracheally intubated, mechanically ventilated, and has a pulmonary artery catheter in place. The following information is available:
   - Heart rate: 140 beats/min
   - Blood pressure: 90/60 mm Hg
   - Central venous pressure (CVP): 10 mm Hg
   - Mean arterial pressure (MAP): 70 mm Hg
   - Pulmonary arterial pressure: 45/25 mm Hg
   - Mean pulmonary arterial pressure: 32 mm Hg
   - Venous oxygen saturation: 65%
   - Pulmonary artery occlusion pressure: 15 mm Hg
   - Carbon monoxide (CO): 3 L/min

   What is the calculated systemic vascular resistance (SVR)?

   A. 1600 dynes sec/cm^5

   B. 30 Woods units

   C. 1200 dynes sec/cm^5

   D. 1200 mm Hg/m^2

   Preferred response: A

Rationale

SVR is calculated by (MAP − CVP)/CO = (70 − 10)/3 = 60/3 = 20 in Woods units. Woods units are converted to dynes sec/cm^5 by a multiplicative factor of 80. Thus 20 × 80 = 1600 dynes sec/cm^5.

4. A 3-year-old child is brought to the emergency department with fever and increasing lethargy during the past 24 hours. On initial evaluation the child is minimally responsive and has poor distal perfusion with cool hands and feet. Blood pressure is 70/30 mm Hg, and oxygen saturation is 85% in room air. The child is intubated, central venous access is obtained, and intravenous fluids are administered. An established goal of continued resuscitation for this child is which of the following?

   A. Achieve a pulmonary artery occlusion pressure of greater than 15 mm Hg

   B. Achieve a central venous pressure (CVP) of 15 mm Hg or higher

   C. Achieve a mixed venous saturation of 70% or higher

   D. Achieve a mean arterial pressure (MAP) of 80 mm Hg or higher

   Preferred response: C

Rationale

Achieving a mixed venous saturation of 70% or higher is one of the goals of early

goal-directed therapy for persons with septic shock. Early goal-directed therapy has been shown to decrease mortality in persons with septic shock.

Chapter 29: Assessment of Cardiovascular Function

---

1. What is a primary determinant of systemic oxygen delivery (DO_2)?

   A. Hemoglobin concentration

   B. Intrathoracic pressure

   C. Oxygen consumption

   D. Pulmonary venous oxygen content

   Preferred response: A

Rationale

DO_2 = Cardiac output (CO) × arterial content of oxygen (CaO_2), where $CaO_2 = (SaO_2 \times \text{Hgb} \times 1.36) + (PaO_2 \times 0.0031)$. Therefore because hemoglobin concentration is a key variable that determines systemic arterial O_2 content, it also is a primary determinant of DO_2.

2. A 3-year-old child with hypoplastic left heart syndrome returns from the operating room following a lateral tunnel fenestrated Fontan procedure. The initial postoperative arterial blood gas shows an oxygen saturation of 80% on a FiO_2 1.0 via the mechanical ventilator. Postoperative chest x-ray is unremarkable, and the echocardiogram shows good right ventricular systolic function, a patent 3-mm fenestration with right-to-left shunting, trace tricuspid regurgitation, no systemic outflow tract obstruction, and an unobstructed Fontan pathway with good flow to both pulmonary arteries. The patient is mildly hypotensive in sinus rhythm with a hemoglobin level of 15 gm/dL and no postoperative bleeding. What is the most appropriate initial management to improve blood pressure and oxygenation?

   A. Cool the patient to decrease oxygen consumption.

   B. Remove the patient from positive pressure mechanical ventilation.

   C. Start an inotropic agent to improve myocardial contractility.

   D. Transfuse with red blood cells to increase hemoglobin.

   Preferred response: B

Rationale

Positive pressure mechanical ventilation decreases systemic venous return and increases pulmonary vascular resistance, both of which are detrimental to Fontan physiology. Spontaneous respiration with negative intrathoracic pressure will provide the optimal conditions for systemic venous return and decreased pulmonary vascular resistance resulting in improved pulmonary blood flow (oxygenation), preload, and cardiac output.

3. A 3-year-old girl with history of a large ventriculoseptal defect is admitted to your pediatric intensive care unit after ventriculoseptal defect closure. A chest radiograph shows that the cardiothoracic ratio is 0.4. The cardiac apex is displaced upward. What is the most likely reason for these radiographic changes?

A. Large pericardial effusion

B. Left ventricular (LV) enlargement

C. Patent foramen ovale

D. Right ventricular (RV) enlargement

Preferred response: D

Rationale

The cardiothoracic ratio gives a quantitative estimate of cardiac size, which is obtained by dividing the transverse measurement of the cardiac shadow in the posteroanterior view by the width of the thoracic cavity. Cardiomegaly is present if this value is greater than 0.5 in adults and 0.6 in infants. Although useful for assessing LV enlargement, the cardiothoracic ratio is not as sensitive to RV enlargement. RV enlargement results in lateral and upward displacement of the cardiac apex on the posteroanterior view and filling of the retrosternal space on the lateral view. It is perhaps more important to know what the chest x-ray may not reveal: Significant cardiac problems, such as constrictive pericarditis, acute fulminant myocarditis, and even acute pericardial tamponade are often associated with a *normal*-sized heart on a chest radiograph.

4. A 1-year-old patient has a hemoglobin of 9 mg/dL and arterial oxygen saturation of 86%. The child's arterial blood gas results reveal the following values: pH, 7.38; pCO_2, 53 mm Hg; and PaO_2, 56 mm Hg. Cardiac output is estimated to be 3.2 L/minute. The child's weight is 10 kg. What is the approximate quantity of oxygen delivered to the tissues in 1 minute (DO_2)?

A. 10 mL O_2/kg/min

B. 20 mL O_2/kg/min

C. 30 mL O_2/kg/min

D. 40 mL O_2/kg/min

Preferred response: C

Rationale

Tissue oxygenation is directly related to both DO_2 and systemic arterial blood pressure. DO_2, the quantity of O_2 delivered to the tissues per minute, is the product of systemic blood flow (SBF), which equals cardiac output except in patients with certain cardiac malformations, and arterial O_2 content:

$$DO_2 \text{ (mL/minute)} = 10 \times CO \text{ (L/minute)} \times C_aO_2 \text{ (mL/100 mL blood)},$$

where CO = cardiac output or SBF in L/min or L/min/m^2 and C_aO_2 = quantity of O_2 bound to hemoglobin plus the quantity of O_2 dissolved in the plasma in arterial blood. The O_2 content of arterial blood (mL O_2/dL blood) equals:

$$C_aO_2 = (S_aO_2 \times Hgb \times 1.36) + (P_aO_2 \times 0.003)$$

where S_aO_2 = arterial O_2 saturation, Hgb = hemoglobin concentration (g/dL), 1.36 (constant) = amount of O_2 bound per gram of hemoglobin (mL) at 1 atmosphere of pressure, P_aO_2 = arterial partial pressure of O_2, and 0.003 (constant) = amount of O_2 dissolved in plasma at 1 atmosphere. The quantity of dissolved O_2 is generally considered to be negligible in the normal range of P_aO_2.

In this case, the CaO_2 is (9 × 1.36 × 0.86) + (0.0031 × 56) = 10.53 + 0.17 = 10.7 mL O_2/100 mL. The DO_2 is therefore 10 × 3.2 × 10.7 = 342.4 mL O_2/min or 34.24 mL O_2/kg/min.

Chapter 30: Myocardial Dysfunction, Extracorporeal Life Support, and Ventricular Assist Devices

---

1. A previously well 8-kg, 6-month-old girl is referred from an outside hospital with frequent episodes of new-onset polymorphic ventricular tachycardia. She has been cardioverted several times and commenced on a lidocaine infusion. The episodes are becoming more frequent and associated with significant hypotension. Echocardiogram reveals extensive left ventricular noncompaction with an ejection fraction of 31%. No intracardiac thrombus is reported. A venous saturation of 51% is obtained from an existing right internal jugular central venous catheter. What would be the appropriate subsequent management?
   A. Cannulate for venoarterial (VA) extracorporeal membrane oxygenation (ECMO) until arrhythmia control is achieved.
   B. Maximize antiarhythmic medication and initiate anticoagulation and milrinone infusion.
   C. Place a left ventricular assist device (LVAD).
   D. Place on VA ECMO as a bridge to longer-term biventricular assist and heart transplantation.

   Preferred response: D

Rationale

Refractory ventricular tachycardia with clinically significant hemodynamic compromise would necessitate biventricular support. The patient has impaired ventricular function with evidence of inadequate tissue oxygen delivery. The

underlying disease process is not amenable to medical therapy alone, and the anticipated duration of mechanical support prior to orthotopic heart transplant would be in the order of weeks to months.

2. A 7-year-old, 22-kg boy is referred to the cardiology clinic with a 5-month history of increasing fatigue, exercise intolerance, anorexia, and dyspnea. His parents comment that his color is gray on minimal exertion. Echocardiography reveals a thin-walled, severely dilated left ventricle with an ejection fraction of 20%. There is moderate mitral regurgitation with an otherwise structurally normal heart and vasculature. A diagnosis of idiopathic dilated cardiomyopathy is made. He is admitted, a central line is placed, and he is started on a milrinone infusion and diuretics. He subsequently develops intermittent unifocal ventricular ectopy. After 24 hours, his parents comment on the improvement in his color, energy levels, and appetite. Listing for heart transplantation is considered. Venous oxygen saturation from his central line is initially 63%. Options for subsequent management include which of the following?

   A. Discharge to home on milrinone with regular visits with the cardiologist.

   B. Place on left ventricular assist device (LVAD) as a bridge to transplant.

   C. Remain in the PICU with current regimen until a donor heart is available.

   D. Wait for evidence of end-organ dysfunction or worsening symptoms of heart failure before intervening.

   Preferred response: A

Rationale

This is a case of a different disease process in an older child where potential clinical improvement can occur in more than 50% of patients. Management will depend on response to initial therapy. Failure to improve clinically in association with evidence of inadequate tissue oxygen delivery will determine the timing of institution of mechanical support. The child's size and expected duration of support precludes an adult VAD system or implantation of a short-term device.

3. You are caring for a newborn who underwent an arterial switch operation for *d*-transposition of the great vessels. Eight hours after surgery, his vital signs are as follows: temperature, 37.8°C; heart rate, 165 beats per minute (sinus rhythm); left atrial pressure, 12 cm H_2O; central venous pressure, 15 cm H_2O; and blood pressure, 54/31 mm Hg. On physical examination, he has slightly cold extremities and pulses are 1+, breath sounds are clear bilaterally, the abdomen is soft, and the liver edge is palpated 3 cm below the right costal margin. Urine output has been 0.49 mL/kg/h for the past 4 hours. Arterial blood gas values show the following: pH, 7.23; pCO_2, 37 mm Hg; PaO_2, 65 mm Hg; base deficit, 6; and lactic acid, 3.7 mmol/L. Which of the following interventions would potentially be detrimental to this patient?

   A. Dopamine, 10 μg/kg/min

   B. Epinephrine, 0.03 μg/kg/min

   C. Fentanyl, 3 μg/kg/h

   D. Milrinone, 0.5 μg/kg/min

Preferred response: A

Rationale

Low cardiac output state (LCOS) is commonly seen after cardiopulmonary bypass and is manifested by oliguria, followed by decreased perfusion, progressive acidosis, and hemodynamic compromise. The goal in management of LCOS is to provide adequate oxygen delivery (DO_2) to the tissues, which can be achieved by decreasing oxygen consumption or increasing DO_2. Maintaining normothermia or mild hypothermia, providing adequate analgesia and sedation, and sometimes neuromuscular blockade are common interventions that will help decreased oxygen consumption.

Phosphodiesterase III inhibitors like milrinone are indicated in the postoperative management of LCOS. Milrinone favors calcium transport into the cell by increasing intracellular cyclic adenosine monophosphate. The increased intracellular calcium enhances the contractile state of the myocyte. Milrinone decreases systemic and pulmonary vascular resistance and improves diastolic relaxation by increasing the rate of calcium reuptake after systole. Although low-dose catecholamines are useful in improving contractility (via their β_1-adrenergic effect), high-dose catecholamines (dopamine >5 μg/kg/min, epinephrine >0.05 μg/kg/min) will increase heart rate and increase systemic vascular resistance, leading to increased myocardial oxygen consumption, decreased cardiac output, and decreased DO_2. If optimized medical management is unsuccessful in reverting LCOS, mechanical support would be indicated.

Chapter 31: Echocardiographic Imaging: Noninvasive Cardiac Diagnostics

1. A patient undergoes surgical repair of tetralogy of Fallot with severe pulmonary stenosis. The postoperative transesophageal echocardiogram demonstrates no residual obstruction in the RV outflow track, with severe pulmonary insufficiency, and a hypertrophied right ventricle. On arrival to the ICU, the patient is noted to be cyanotic. Breath sounds are equal with appropriate readings on ventilator monitors. Which of the following would be an ideal early evaluation or intervention for this infant?

   A. Increase the FiO_2 on the ventilator to 100% and hope the cyanosis resolves.

   B. Obtain an echocardiogram to evaluate for right-to-left shunting at the atrial level.

   C. Request that the surgeon take the patient back to the operating room immediately.

   D. Request that an interventionalist take the infant to the catheterization laboratory for device occlusion of a presumed right-to-left shunt.

Preferred response: B

Rationale

Echocardiography is useful (and the modality of choice) in the evaluation of the cyanotic patient, can often be quickly and easily obtained, and gives immediate answers on residual shunts in the postoperative patient. Prior to taking the infant back for revision of the operation, or to the catheterization laboratory for intervention, it is useful to understand the etiology of the cyanosis. An atrial level communication is at times left intentionally to allow a "pop-off" for the stiff right ventricle in the immediate postoperative period. A chest x-ray would be obtained prior to repositioning the ETT rather than assuming malposition in the setting of equal breath sounds. Increasing the FiO_2 to 100% is not a long-term solution.

2. Which of the following statements is true regarding echocardiography?
   A. Echocardiography is limited to available acoustic windows.
   B. Echocardiography is uniquely a noninvasive modality.
   C. Echocardiography provides precise measurements of pulmonary arterial pressures.
   D. Echocardiography can provide histologic evaluation of cardiovascular tissues.
   Preferred response: A

Rationale

Echocardiography is limited to the "windows" where the ultrasound beam can penetrate adequately to produce images. It does not penetrate well through air. This can be a major limitation to echocardiography. The remaining statements are not true. Transesophageal (TEE) and intracardiac echo (ICE) are examples of invasive echocardiography. Echocardiography provides estimates of pulmonary arterial pressures, which can be inaccurate for many different reasons.

3. What is the earliest gestational age that cardiac echocardiography can be used to assess fetal cardiac anatomy reliably?
   A. 8 weeks
   B. 14 weeks
   C. 20 weeks
   D. 28 weeks
   Preferred response: C

Rationale

Complete anatomic and physiologic assessment can be obtained in the neonate and in the fetus at 20 weeks of gestation.

4. Which of the following is the mainstay of the anatomic diagnosis of congenital heart disease?
   A. Angiography
   B. Cardiac catheterization

C. Computerized tomographic angiography

D. Echocardiography

Preferred response: D

Rationale

The technique of echocardiography and the practice of *echocardiology* have changed the practice of pediatric cardiology by largely replacing the use of cardiac catheterization/angiography for the diagnosis of congenital malformations. Combined with the use of prostaglandin for maintaining the patency of the ductus arteriosus, echocardiography has dramatically reduced the need for emergency cardiac catheterization in neonates. Most patients with congenital heart disease that is detected in the neonatal period can undergo palliative surgery without cardiac catheterization. Most definitive surgical repairs can be performed successfully without the risk of invasive studies. Pulsed, continuous-wave, color, and tissue Doppler have added important capabilities for anatomic and functional assessment. Intraoperative and postoperative management of congenital heart defects has been aided by the addition of transesophageal echocardiography.

5. Right ventricular pressure can be estimated with the use of echocardiography by the simplified Bernoulli equation, where v is peak velocity of which insufficiency jet?

A. Pulmonary insufficiency jet $4v$

B. Pulmonary insufficiency jet $2v$

C. Tricuspid insufficiency jet $4v^2$

D. Tricuspid insufficiency jet $2v^2$

Preferred response: C

Rationale

Estimation of right ventricular systolic pressure by Doppler echocardiography is done with use of the maximum velocity (v) of the regurgitant tricuspid jet. The systolic pressure gradient (delta P) between the right ventricle and the right atrium is calculated by using the simplified Bernoulli equation (delta P = $4v^2$).

6. Segmental analysis of cardiac disease is classically based on which of the following?

A. Great vessel arrangement, ventricular looping, situs

B. Situs, great vessel arrangement, ventricular looping

C. Situs, ventricular looping, great vessel arrangement

D. Ventricular looping, great vessel arrangement, situs

Preferred response: C

Rationale

Comprehensive analysis of cardiovascular anatomy requires a step-by-step segmental approach. A complete, step-by-step approach to cardiac diagnosis includes the diagnosis of atrial situs; identification of the chambers and their

interconnections; and systematic assessment of valves, septa, coronaries, systemic and pulmonary veins, and aortic anatomy. Imaging of the thymus and diaphragm is part of the detailed echocardiographic examination.

The segmental approach is based on the principle that all aspects of abnormal cardiovascular morphology can be broken down into discrete, mutually exclusive descriptors, allowing unambiguous delineation of any complex congenital malformation. The schema must include information on the presence, position, and connection of each cardiac segment. Classically, three segments have been recognized: atria, ventricles, and great arteries. By describing the anatomic segments and indicating the normality or abnormality of each, a complete description of the cardiac anatomy is possible. It now is possible to code cardiac anatomic abnormalities by segmental analysis.

Determination of cardiac position and atrial-visceral situs is a standard portion of the echocardiographic assessment of congenital heart disease and is the foundation of the segmental approach. Atrial situs and atrial morphology are diagnosed together, and four possibilities exist: solitus (normal), inversus, and heterotaxy that may be right atrial isomerism or left atrial isomerism.

Description of the connection of the atria and ventricles (ie, AV connection) requires knowledge of both atrial and ventricular morphology. Four patterns of AV connection exist: concordant (ie, normal); discordant; univentricular through a single inlet (ie, tricuspid or mitral atresia), double inlet, or common inlet; and ambiguous (ie, two ventricles with atrial isomerism). When the morphologic right atrium connects normally to the morphologic right ventricle and the left atrium connects to the left ventricle, AV concordance is present. When this connection is reversed and the morphologic right atrium connects to the morphologic left ventricle, AV connection is discordant and sometimes is referred to as ventricular inversion.

Ventriculoarterial connection is the manner in which the great arteries and semilunar valves connect to the ventricular outflow tracts. Normally, the morphologic right ventricle connects to the pulmonary valve and the morphologic left ventricle connects to the aortic valve. Four possibilities exist: concordant (ie, normal), discordant (ie, right ventricle to the aorta and left ventricle to the pulmonary trunk), double outlet (usually the right ventricle), and single outlet (ie, aortic or pulmonary atresia or truncus arteriosus).

7. Ventricular function can be assessed by the shortening fraction. Shortening fraction is calculated by which of the following equations?
   A. End-diastolic dimension minus end-systolic dimension divided by end-diastolic dimension
   B. End-diastolic dimension minus end-systolic dimension divided by end-systolic dimension
   C. End-systolic dimension minus end-diastolic dimension divided by end-systolic dimension
   D. End-systolic dimension minus end-diastolic dimension divided by end-diastolic dimension

   Preferred response: A

Rationale

Echocardiography is a tomographic anatomic tool, but it also provides dynamic information about cardiac function and structure. Observations about the cardiac walls, including their movement, thickness, and degrees of shortening and thickening, can be extremely useful in determining segmental and global cardiac function. In general, the shortening fraction of the left ventricle should be at least 28% (end-diastolic minus end-systolic divided by end-diastolic dimension), and the walls of the left ventricle should move inward symmetrically.

8. In congenital heart disease, the major application of contrast echocardiography in the postoperative patient is which of the following?

A. Assessment of ventricular function

B. Assessment of coronary arterial flow

C. Detection of residual shunt lesion

D. Evaluation of mitral regurgitation

Preferred response: C

Rationale

An ultrasonic contrast agent is a substance that stabilizes microbubbles in solution, which are large enough to reflect ultrasound but small enough that they disappear rapidly and are physiologically safe. The agent may be as simple as an injection of saline solution into the circulation during two-dimensional echocardiographic imaging or as complex as precision-engineered microbubbles of polysaccharide that dissolve in the circulation after injection. Advances in bubble technology allow imaging of myocardial capillary perfusion. Contrast also can be useful in defining the identity of an imaged structure. For example, a structure under the aortic arch may be confusing but can be confirmed to be the innominate vein by echocardiographic contrast injection in a left arm vein. In persons with congenital heart disease, the major application of contrast echocardiography is in the postoperative patient with residual shunts or as a means to exclude congenital heart disease. Systemic venous injection of contrast fills the right side of the heart sequentially, and the site of residual right-to-left shunting can be defined.

9. The Ross procedure involves which of the following?

A. Autologous autograft in the pulmonary position and mechanical prosthesis in the aortic position

B. Autologous autograft in the aortic position and mechanical prosthesis in the pulmonary position

C. Mechanical valve in the pulmonary position and autograft in the aortic position

D. Placement of a pulmonary autograft in the aortic position

Preferred response: D

Rationale

The Ross procedure involves the substitution of the diseased aortic valve with the patient's own pulmonary valve (autograft). A pulmonary homograft is then used to replace the patient's pulmonary valve. The coronary arteries are translocated to the new aortic valve. Advantages of this procedure include the lack of need for

anticoagulation because of the decreased incidence of thromboembolism, as well as growth of the valve as the child grows. One disadvantage is the treatment of one-valve disease with a two-valve replacement.

Chapter 32: Diagnostic and Therapeutic Cardiac Catheterization

1. A 6-month-old infant is 4 days into the postoperative period after tetralogy of Fallot repair. There are persisting signs of right heart failure with hepatomegaly and ascites. An echocardiogram has inadequate windows to visualize the branch pulmonary arteries. What is the most appropriate management?
   A. Communicate to the cardiac surgeon and interventional cardiologist and advocate for a diagnostic catheterization and possible pulmonary artery intervention if significant residual stenotic lesions are diagnosed.
   B. Communicate to the cardiac surgeon and interventional cardiologist and advocate for a diagnostic catheterization and possible ASD closure.
   C. Continue to medically manage with the goal of spontaneous right heart recovery.
   D. Transfer the infant to the catheterization laboratory for pulmonary artery angiography.
   Preferred response: A

Rationale

Communication is essential. The cardiac surgeon on a recent surgical patient will know the child's anatomy intimately and also have an awareness of possible problems. The interventional cardiologist can advise on what is technically feasible. As the ICU attending, involving all providers is crucial for maximizing outcomes.

Arranging a catheterization without consultation will result in a poorly planned and inefficient catheterization that may lead to unnecessary angiograms and worse outcomes. Right heart failure can spontaneously improve early after cardiac repair, but if recovery is prolonged 72 hours longer than anticipated, then strong consideration for residual cardiac defects is very important. There are now reports on safe early postoperative interventions, thus a catheterization for merely diagnostic purposes would be incorrect. Closing an ASD in the setting of right heart failure would worsen cardiac output and elevate central venous pressure. In fact if there is an intact atrial septum, one of the interventions to consider is creating an ASD.

2. When should cardiac surgical patients requiring venoarterial (VA) extracorporeal membrane oxygenation (ECMO) in the postoperative period be considered for cardiac catheterization?
   A. If there is left ventricle (LV) dysfunction, left atrial (LA) dilation, and pulmonary edema on chest radiograph
   B. Never; cardiac catheterization due to risks of the procedure and transportation

is contraindicated when cannulated for VA ECMO

C. Only as a last resort and should not be considered unless unable to be decannulated after 2 weeks

D. Should not be considered unless unable to be decannulated after 1 week

Preferred response: A

Rationale

Left atrial decompression can be safely achieved in the catheterization laboratory and is important in the setting of LV dysfunction with distention. Decompression of the LA with interventional techniques (placing a cannula in the LA, creating an ASD) alleviates this problem. The other option is placement of a LA cannula by cardiac surgery and, this may be preferable in a small child with an open chest.

Safe transport is challenging but should not be the deciding factor. Catheterization on VA ECMO requires a high degree of teamwork, particularly with transport to ensure that cannula position remains stable. Safe transportation is a reality in many centers. Procedural risks even with anticoagulation are minimal. It is important to have a high index of suspicion for residual lesions in postoperative cardiac surgery patients who cannot be weaned from ECMO. Unless there is clear evidence for myocardial recovery, consideration for catheterization by the ICU attending and direct consultation with cardiac surgery and interventional cardiology should occur early and within 72 hours of the start of the unexpected course. Interventions can be performed on VA ECMO and would be indicated if any residual lesions are diagnosed.

3. For an early postoperative patient who has persistent low cardiac output and is unable to be weaned from the ventilator, cardiac catheterization is characterized by which of the following?

A. Carries a significantly increased risk of serious adverse events when compared with late postoperative catheterization

B. May yield important physiologic and anatomic information that often leads to reintervention

C. Should only be performed on a patient supported with extracorporeal membrane oxygenation (ECMO)

D. Should be deferred until 6 weeks following surgery

Preferred response: B

Rationale

Cardiac catheterization should always be considered in the early postoperative period when a patient exhibits a persistent low output state or failure to wean from mechanical ventilation. Early postoperative catheterization often yields important physiologic and anatomic information and frequently leads to reintervention. Whereas elective catheter-based interventions are typically deferred until 6 weeks following surgery, the risk-benefit ratio favors early postoperative catheterization for the patient who does not follow a projected course. ECMO is used in postoperative patients who fail to separate from bypass or have progressive low output. These patients often require early postoperative catheterization to assess unfavorable

physiology. In addition, ECMO support is often used to safely support the circulation in patients for whom a high-risk catheter intervention is planned. In the hands of an experienced team (ie, interventional cardiologist, intensivist, anesthesia personnel, and nursing staff), serious adverse event rates are similar for early or late postoperative studies.

4. A balloon atrial septostomy in the preoperative patient with d-TGA is characterized by which of the following?

   A. Increases left atrial hypertension

   B. May increase the risk for pulmonary hypertension prior to cardiac surgery

   C. May be performed under fluoroscopic or echocardiographic guidance

   D. Worsens cyanosis by facilitating mixing at the atrial level

   Preferred response: C

Rationale

Balloon atrial septostomy should be considered in any newborn with a confirmed diagnosis of d-TGA who demonstrates inadequate mixing at the atrial level. Signs of inadequate mixing include cyanosis, left atrial hypertension, and pulmonary hypertension. Balloon atrial septostomy improves cyanosis by facilitating mixing at the atrial level, reduces left atrial hypertension, and may reduce the risk for pulmonary hypertension prior to cardiac surgery. Balloon atrial septostomy may be performed in the catheterization laboratory (under fluoroscopic guidance) or in the intensive care unit (under echocardiographic guidance) at the discretion of the intensivist and catheterizer.

Chapter 33: Pharmacology of the Cardiovascular System

---

1. A 4-month-old male with Down syndrome is admitted to the PICU for postoperative care following patch repair of a large ventricular septal defect (VSD). He was managed preoperatively for congestive heart failure with furosemide and enalapril. His vital signs on admission to the PICU are significant for a temperature of 38.2°C; heart rate, 170 beats per minute; blood pressure, 86/38 mm Hg via a right radial arterial catheter (mean arterial pressure, 54 mm Hg); and oxygen saturation of 89% by pulse oximetry (with a probe on his great toe). On exam, his extremities are mottled and cool distally, with a capillary refill of 2.5 seconds. A bedside arterial blood gas suggests adequate oxygenation and ventilation. The arterial lactate is 6 mmol/L. You observe only a marginal change in his perfusion after three fluid boluses of 10 mL/kg. The central venous pressure is now 14 mm Hg. What is the most appropriate next step in his management?

   A. Administer an intravenous (IV) milrinone bolus of 50 μg/kg over 15 minutes followed by a continuous infusion of milrinone at 0.5 μg/kg/minute.

   B. Continue to bolus with fluids, but change to albumin for more effective intravascular volume repletion.

C. Start epinephrine at 0.5 μg/kg/minute, titrating to achieve a goal mean arterial pressure of 65 mm Hg.

D. Start dopamine at 15 μg/kg/minute, and overdrive pace to ensure atrioventricular synchrony.

Preferred response: A

Rationale

This patient is exhibiting signs of postoperative, decompensated cardiogenic shock, with tachycardia, cool and mottled extremities, prolonged capillary refill, and an elevated lactate, all of which indicate inadequate cardiac output. The decreased saturation via pulse oximetry, while the arterial blood gas demonstrates adequate oxygenation, is a function of distal vasoconstriction, which impacts the ability of the pulse oximeter probe to provide an accurate reading. Fluid resuscitation was attempted to augment preload, to optimize this patient's ventricular filling (to take advantage of the Starling relationship), but it did not restore perfusion because there is significant myocardial dysfunction. Therefore the best intervention is to start milrinone, which provides both inotropy and afterload reduction, without significantly increasing myocardial oxygen demand. If a patient's blood pressure and hemodynamics allow, a loading dose is given before initiating the infusion.

A catecholamine such as epinephrine, as a sole agent and initiated at the dose provided in the scenario, would not be the best option for several reasons. First, the patient is already tachycardic, and epinephrine at 0.5 μg/kg/minute may increase the heart rate further and increase myocardial oxygen demand in a heart whose function is already impaired. Escalating this patient's heart rate would also decrease the diastolic interval for ventricular filling, thus compromising cardiac output even further.

In addition, patients who undergo repair of large ventricular septal defects are at increased risk for developing junctional ectopic tachycardia (JET), a tachyarrhythmia unique to the postoperative state in children, in which the loss of atrioventricular synchrony compromises cardiac output. Patients in whom this rhythm is poorly tolerated may require treatment with antiarrhythmics and active cooling if conservative measures such as avoiding fever and minimizing catecholamine-induced increases in adrenergic tone fail.

Response B would not be the most appropriate next step because the central venous pressure is already elevated due to ventricular dysfunction, and rather than augmenting cardiac output, additional fluid boluses would likely produce pulmonary edema.

High-dose dopamine, response D, would not be the best choice for similar reasons as those stated for epinephrine. In addition, at a dose of 15 μg/kg/minute, dopamine exhibits strong α-adrenergic (vasoconstrictive) properties, which would increase afterload and compromise distal perfusion even further. The consequences of increasing heart rate with overdrive pacing were detailed earlier.

2. Norepinephrine ____________ the heart rate. This action is mediated by ____________. Therefore ____________ would be an effective agent for reversing this response.

A. Increases, the hypothalamus, isoproterenol

B. Decreases, a reflex response, atropine

C. Decreases, a vagal response, isoproterenol

D. Has no effect on, the sinus node, ventricular pacing

Preferred response: B

Rationale

Norepinephrine exhibits strong α-adrenergic properties at doses used to reverse vasodilatory (hyperdynamic) shock. The resulting increase in vascular tone triggers a compensatory vagally mediated reflex slowing of the heart, which atropine will reverse via a muscarinic receptor blockade. Neither the hypothalamus nor the sinus node has been implicated.

3. You have decided to add an epinephrine infusion to the management of an 11-year-old girl with myocarditis. Your goal is to improve cardiac contractility via epinephrine's effect on β receptors. A medical student on call with you asks why epinephrine is more selective for β receptors than norepinephrine. How do you respond to this question?

A. Because of an increased number of hydroxyl groups on the phenylethylamine core

B. Because of a decrease in size of the substituent on the amino group

C. Because of an increase in size of the substituent on the amino group

D. Because of a lack of hydroxyl group at position 4 on the phenylethylamine core

Preferred response: C

Rationale

Increasing the size of the substituent on the amino group enhances β selectivity, while decreasing the size favors α selectivity. Hydroxyl groups are the same in terms of number and location for all catecholamines.

4. Catecholamines and phosphodiesterase III (PDE III) inhibitors share a common mechanism in that both groups of agents do which of the following?

A. Decrease intracellular calcium in the vascular smooth muscle

B. Decrease the activity of protein kinase A

C. Increase the activity of adenylate cyclase

D. Increase the levels of cyclic adenosine monophosphate (cAMP) in the cardiac myocyte

Preferred response: D

Rationale

Catecholamines vary in terms of their effect on intracellular calcium in the vascular smooth muscle. PDE III inhibitors increase activity of adenylate cyclase. Both groups of drugs increase levels of the second messenger, cAMP.

5. You are taking care of a 6-month-old boy in the immediate postoperative period of a ventricular septal defect repair. The infant is normotensive but has decreased

perfusion. You wish to add an inotropic agent. Which statement best describes an inotropic agent?

A. Inotropic agents primarily increase blood pressure.

B. Inotropic agents primarily increase systemic vascular resistance.

C. Inotropic agents primarily increase stroke work.

D. Inotropic agents primarily decrease myocardial oxygen consumption.

Preferred response: C

Rationale

Inotropic agents increase stroke work at a given preload and afterload; they do not necessarily increase blood pressure. Vasopressor agents increase blood pressure by increasing systemic vascular resistance. Inotropic agents may increase or decrease myocardial oxygen consumption, depending on the clinical scenario.

6. What is the result of an increase in cAMP in vascular smooth muscle?

A. Inhibition of uptake of calcium by sarcoplasmic reticulum with resultant vasoconstriction

B. Inhibition of uptake of calcium by sarcoplasmic reticulum with resultant vasodilation

C. Uptake of calcium by sarcoplasmic reticulum with resultant vasoconstriction

D. Uptake of calcium by sarcoplasmic reticulum with resultant vasodilation

Preferred response: D

Rationale

In vascular smooth muscle, both β_1 and β_2 receptors are present, although β_2 receptors predominate. The β_2 receptor is coupled to G_s; therefore activation of β_2 receptors promotes formation of cAMP. The resulting activation of cAMP-dependent protein kinase in vascular smooth muscle, however, stimulates pumps that remove calcium from the cytosol and also promotes calcium uptake by the sarcoplasmic reticulum. As cytosolic calcium concentration decreases, smooth muscle relaxes and the blood vessel dilates. Adrenergic receptors also have been demonstrated on the endothelium and are capable of producing relaxation of the vessel. The exact mechanism involved, including the role of nitric oxide and the subtype of β receptors involved, remain under investigation.

7. What is the result of an increase in cAMP in myocyte?

A. Closing of voltage-gated calcium channels with a decrease in inotropy

B. Opening of voltage-gated calcium channels with an increase in inotropy

C. Uptake of calcium by the sarcoplasmic reticulum with a resultant decrease in the force of the next contraction

D. Uptake of calcium by the sarcoplasmic reticulum with a decrease in lusitropy

Preferred response: B

Rationale

Adrenergic receptors are typically coupled to one of three types of G proteins: G_s, G_i, or G_q. G_s proteins produce an increase in adenylate cyclase activity, whereas G_i proteins promote a decrease in adenylate cyclase activity. G_q protein receptors stimulate phospholipase C to generate diacylglycerol and inositol 1,4,5-triphosphate (IP_3).

Myocardial β_1-adrenergic receptors are associated with G_s. When an agonist agent engages this receptor type, the result is enhanced activity of adenylate cyclase and a rise in the concentration of cAMP, which activates protein kinase A (PKA). PKA in turn phosphorylates voltage-dependent calcium channels, increasing the fraction of channels that can be open and the probability that these channels are open, producing an increase in intracellular calcium concentration. Calcium then binds to troponin C, allowing for actin-myosin cross-bridge formation and sarcomere contraction. Also, PKA phosphorylates phospholamban, relieving the disinhibitory effect of the unphosphorylated form on calcium channels in the sarcoplasmic reticulum. The accumulation of calcium by the sarcoplasmic reticulum is thus enhanced, increasing the rate of sarcomere relaxation (lusitropy) and subsequently increasing the amount of calcium available for the next contraction. This leads to both enhanced contractility and active diastolic relaxation.

8. Activation of V_1 receptors by arginine vasopressin (AVP) results in which of the following?

A. Stimulation of G_q protein and activation of phospholipase C

B. Stimulation of G_s protein and an increase in cAMP

C. Stimulation of G_s protein and a decrease in cAMP

D. Stimulation of G_i protein and an increase in cGMP

Preferred response: A

Rationale

Vasopressin receptors belong to the family of G protein–coupled receptors. V_1 receptors are coupled to G_q, and V_2 receptors are coupled to G_s. When vasopressin binds to the V_1 receptor, phospholipase C (PLC) is activated with the eventual production of inositol 1,4,5-triphosphate (IP_3) and 1,2 diacylglycerol (1,2 DG). These molecules increase the release of calcium from the endoplasmic reticulum and increase the entry of calcium through gated channels. The increase in intracellular calcium leads to an increase in the activity of myosin light chain kinase. This kinase acts on myosin to increase the number of actin-myosin cross-bridges, enhancing contraction of the myocyte. Of note, vasopressin has been shown to produce vasoconstriction in the skin, skeletal muscle, and fat while producing vasodilatation in the renal, pulmonary, and cerebral vasculature. This effect may be mediated though nitric oxide or may be a function of the isoform of adenyl cyclase with which the receptor is coupled. AVP also has been shown to increase the pressor effects of catecholamines, although in two different vascular smooth muscle cell lines, AVP had opposing effects on isoproterenol-induced activation of adenyl cyclase.

9. Which of the following drugs has the least effect on increasing myocardial oxygen

consumption?

A. Dopamine

B. Dobutamine

C. Epinephrine

D. Milrinone

Preferred response: D

Rationale

With the exception of the bipyridines (amrinone, milrinone), all inotropes increase myocardial oxygen consumption because they increase myocardial work.

10. Which of the following drugs worsens intrapulmonary shunt in acute respiratory distress syndrome?

A. Atropine

B. Digoxin

C. Dopamine

D. Milrinone

Preferred response: C

Rationale

Dopamine depresses the ventilatory response to hypoxemia and hypercarbia by as much as 60%. Dopamine (and other β agonists) decreases PaO_2 by interfering with hypoxic vasoconstriction. In one study, dopamine increased intrapulmonary shunting in patients with acute respiratory distress syndrome from 27% to 40%.

11. Which of the following drugs may cause a decrease in heart rate?

A. Dopamine

B. Epinephrine

C. Isoproterenol

D. Norepinephrine

Preferred response: D

Rationale

Norepinephrine produces increases in systemic vascular resistance (SVR), arterial blood pressure, and urine flow. It is most valuable in the context of tachycardia because infusion of the drug does not produce significant elevation of heart rate and may even lower heart rate through reflex mechanisms. In a study of adults with abdominal sepsis, norepinephrine infusion was associated with increases in systemic blood pressure and SVR. Stroke volume increased as the heart rate declined. The cardiac index did not change, although creatinine clearance increased substantially. Norepinephrine has been shown to improve right ventricular performance in adults with hyperdynamic septic shock.

12. Which of the following statements is true regarding the origin of these pharmacologic agents?

A. Arginine vasopressin is synthesized in the posterior pituitary.

B. Dobutamine is synthesized in the adrenal medulla from norepinephrine.

C. Dopamine is the immediate precursor of norepinephrine in the adrenal medulla.

D. Norepinephrine is synthesized in the adrenal medulla from epinephrine.

Preferred response: C

Rationale

- Dopamine is a central neurotransmitter. It also is found in the sympathetic nerve terminals and in the adrenal medulla, where it is the immediate precursor of norepinephrine. Dopamine is hydroxylated at the β-carbon to produce norepinephrine, the principal neurotransmitter of the sympathetic nervous system.
- Arginine vasopressin is a nonapeptide hormone synthesized in the supraoptic and paraventricular nuclei of the hypothalamus.
- Dobutamine is a synthetic catecholamine.
- Isoproterenol is the synthetic N-isopropyl derivative of norepinephrine.

13. An epinephrine infusion may result in which of the following adverse effects?

A. Hypercalcemia

B. Hyperkalemia

C. Hypocalcemia

D. Hypokalemia

Preferred response: D

Rationale

Hypokalemia is produced by an epinephrine infusion because of stimulation of β_2-adrenergic receptors, which are linked to sodium-potassium-adenosine triphosphatase (ATPase) located in skeletal muscle. Infusion of 0.1 μg/kg/min lowered serum potassium by 0.8 mEq/L. Hyperglycemia results from β-adrenergic–mediated suppression of insulin release.

14. Which of the following adverse effects is the most likely result of an isoproterenol infusion?

A. Bradycardia

B. Bronchoconstriction

C. Decrease in myocardial oxygen consumption

D. Decrease in serum theophylline concentrations

Preferred response: D

Rationale

Isoproterenol enhances cardiac contractility and cardiac rate. Peripheral vasodilatation produces a decrease in SVR, augmenting the direct chronotropic

action of the drug. Significant tachycardia ensues. Systolic blood pressure increases, while mean and diastolic pressures decrease. If normal prior to infusion of isoproterenol, mesenteric and renal perfusions decrease; however, if the subject was in shock, then the increase in cardiac output associated with isoproterenol administration may result in an increase in blood flow to these tissues. Isoproterenol increases myocardial demand for oxygen and decreases supply by reducing diastolic coronary filling. If intravascular fluid of the patient is depleted, hypotension may complicate initiation of isoproterenol infusion.

Pulmonary bronchial and vascular bed β_2-adrenergic receptors produce bronchodilation and pulmonary vasodilatation, respectively.

Adverse effects associated with isoproterenol include fear, anxiety, restlessness, insomnia, and blurred vision. Other effects may include headache, dizziness, tinnitus, sweating, flushing, pallor, tremor, nausea, vomiting, and asthenia. Cardiovascular effects may include ventricular tachycardia and other ventricular dysrhythmias that may be life threatening. Isoproterenol may cause hypertension and also can cause severe hypotension.

Isoproterenol decreases serum theophylline concentrations during concomitant therapy of status asthmaticus, and thus it may be necessary to increase theophylline dosage when isoproterenol therapy is initiated and reduce theophylline dosage when isoproterenol is discontinued.

15. Which of the following is the major method of metabolism/elimination of milrinone?

A. Hepatic glucuronidation

B. Metabolism by catechol *O*-methyltransferase (COMT)

C. Metabolism by *N*-acetyltransferase

D. Renal **e**xcretion

Preferred response: D

Rationale

- Milrinone is approximately 70% bound to plasma proteins, with approximately 85% renal elimination. Hepatic glucuronidation accounts for a minor elimination pathway. Both renal dysfunction and congestive heart failure affect the elimination profile of milrinone, extending the elimination half-life to approximately 2 hours.
- Amrinone is metabolized by *N*-acetyltransferase.
- Epinephrine is metabolized by COMT to metanephrine in the liver and kidneys or deaminated via the action of MAO.
- Dopamine and dobutamine are metabolized by COMT and MAO.

16. What is the mechanism of action for digitalis?

A. Closure of voltage-gated calcium channels

B. Closure of K channels

C. Inhibition of sodium/potassium (Na/K)-ATPase

D. Opening of voltage-gated calcium channels

Preferred response: C

Rationale

Glycosides bind to and inhibit Na/K-ATPase. Binding of digoxin to ATPase is affected by serum potassium. Hyperkalemia depresses digoxin binding, whereas hypokalemia has the opposite effect, accounting in part for potentiation of digoxin-induced dysrhythmias during hypokalemia. Inhibition of ATPase produces an increase in intracellular calcium and enhances the inotropic state of the myocardium.

17. Which of the following abnormalities potentiates digitalis toxicity?

A. Hypercalcemia

B. Hyperkalemia

C. Hypocalcemia

D. Hypokalemia

Preferred response: D

Rationale

Digitalis toxicity is made more likely by factors that increase myocardial irritability, such as myocarditis, ischemia, hypoxemia, or catecholamine support. Hypokalemia and alkalosis also potentiate digoxin-induced dysrhythmias. Treatment of digoxin toxicity involves supportive treatment and correction of electrolyte disturbances. Specific pharmacologic support (via atropine, lidocaine, phenytoin, or magnesium sulfate) may be necessary (although frequently unsuccessful), and in life-threatening circumstances, treatment with digoxin-specific Fab antibody fragments is indicated.

Chapter 34: Cardiopulmonary Interactions

---

1. Why would positive pressure ventilation be expected to increase left ventricular stroke volume and cardiac output in patients with left ventricular systolic dysfunction?

A. In expiration, positive pressure ventilation propels forward coronary blood flow.

B. In patients with systolic ventricular dysfunction, the proportion of lung units with zone III conditions (pulmonary venous pressure > alveolar pressure) exceeds that of the normal circulation.

C. Positive airway pressure reduces left ventricular afterload.

D. Positive airway pressure raises transmural left atrial pressure.

Preferred response: C

Rationale

Positive pressure ventilation raises juxtacardiac pressure. This reduces the left

ventricular wall tension needed to generate systolic pressure within the left ventricle sufficient to open the aortic valve. In effect, positive juxtacardiac pressure reduces afterload to the left heart. Positive pressure ventilation also reduces demand for cardiac output, but this does not, itself, increase cardiac output. Positive airway pressure would not be expected to propel forward coronary blood flow. There would be an increase in zone III lung units when pulmonary venous pressure is elevated, and this might blunt the rise in pulmonary vascular resistance attributable to alveolar capillary compression. Overall, a rise in juxtacardiac pressure would be expected to reduce transmural atrial pressure.

2. Which of the following mechanisms mediates the positive pressure ventilation (PPV)-induced rise in right ventricle (RV) afterload?
   A. A compensatory increase in the mean systemic pressure (Pms)
   B. An increase in the proportion of lung units under zone III conditions (Pv > Ps)
   C. Compression of alveolar vessels
   D. Hypoxic pulmonary vasoconstriction
   Preferred response: C

Rationale

Most of the alveolar surface is laced with a network of alveolar capillaries coursing within the alveolar septum. These sheets of epithelium and vessels lie between adjacent alveoli, so they are subject to the airway pressure that functionally surrounds them. Positive airway pressure compresses alveolar capillaries when alveolar pressure exceeds pulmonary capillary pressure, reducing the driving pressure that propels blood from pulmonary artery to pulmonary vein. There are also corner vessels that traverse the intersection of alveolar septae. These vessels are stretched and stented open at lung volumes above functional residual capacity, whether the lung is stretched by positive pressure or by spontaneous inspiration. This stenting of corner vessels reduces pulmonary vascular resistance. Positive airway pressure has little direct effect on mean systemic pressure but may, over a period of time, cause it to rise. A rise in Pms would increase venous return but would not increase right ventricular afterload. Hypoxic pulmonary vasoconstriction is a potent mechanism to alter the distribution of blood flow through the lungs. It does raise right ventricular afterload, but alveolar hypoxia should be reduced by positive pressure ventilation, not accentuated. As the lung is distended by positive airway pressure, the proportion of lung subject to zone III conditions is reduced, not increased. This reduction would raise right ventricular afterload.

3. Pulsus paradoxus is an exaggeration of the normal version of which of the following?
   A. Fall in systolic arterial pressure during spontaneous inspiration
   B. Fall in right ventricular filling during spontaneous inspiration
   C. Rise in aortic ejection velocity during spontaneous inspiration
   D. Rise in right ventricular stroke volume during spontaneous inspiration
   Preferred response: A

Rationale

Pulsus paradoxus is an exaggeration of the fall in systolic arterial pressure that normally occurs during spontaneous inspiration. It is a classical finding in pericardial tamponade but also occurs when pleural pressure drops precipitously during strained inspiration (eg, in persons with croup, asthma, or pneumonia). In tamponade, end-diastolic cardiac volume is essentially fixed. Inspiration favors filling of the right side of the heart over filling of the left side of the heart, shifting the interventricular septum to the left and reducing left ventricular distention. This phenomenon decreases contractility by the Starling mechanism. Inspiration also increases left ventricular afterload by reducing juxtacardiac pressure. Restricting total cardiac volume accentuates these normal effects. Respiratory distress can accentuate these effects by the same mechanisms.

Pulsus paradoxus during tamponade was defined before the advent of modern invasive monitoring. It was the appearance and disappearance of the Korotkoff sound over the respiratory cycle that defined the phenomenon. As the pressure in the cuff fell, the first appearance of the Korotkoff sound signaled the expiratory arterial pressure. As the mercury continued to fall, the sound went from intermittent to regular and more frequent when the inspiratory systolic pressure was reached, and it could be heard with every beat of the heart. Although there should be an associated rise in right ventricular stroke volume, that finding is not the defining event in tamponade.

4. Positive pressure inspiration does which of the following?
   A. Compresses alveolar capillaries
   B. Increases left ventricular afterload
   C. Raises mean systemic pressure
   D. Shifts the interventricular septum toward the left
   Preferred response: A

Rationale

Positive pressure inspiration compresses alveolar capillaries. This action may raise pulmonary vascular resistance, which is least at functional residual capacity. On the other hand, positive pressure inspiration generally reduces left ventricular afterload by raising juxtacardiac pressure. Under most circumstances, positive pressure inspiration reduces right ventricular filling and shifts the interventricular septum to the right. It has virtually no effect on mean systemic pressure, which is the driving force for systemic venous return. As a rule, positive pressure inspiration increases aortic diastolic pressure, but not by as much as it raises arterial systolic pressure, and thus pulse pressure generally widens.

Chapter 35: Disorders of Cardiac Rhythm

---

1. A 4-month-old child presents to the intensive care unit following operative repair

of tetralogy of Fallot in complete AV block with an atrial rate of 120 bpm and a wide complex ventricular escape rate of 50 bpm. Temporary epicardial pacing wires were placed on the right atrium and right ventricle during surgery, with acceptable sensing and pacing characteristics. What would be the best immediate management step?

A. Temporary AAI pacing

B. Temporary VOO pacing

C. Temporary DDD pacing

D. Placement of a transvenous dual chamber permanent pacemaker

Preferred response: C

Rationale

With acceptable atrial and ventricular sensing and pacing, dual chamber pacing is the preferred pacing mode. AAI pacing would be inappropriate in the setting of AV block. Temporary VOO pacing is associated with an increased risk of inducing ventricular tachycardia or fibrillation. Placement of a permanent pacemaker system would be inappropriate on postoperative day 1, given that AV nodal conduction may recover.

2. What is the most common mechanism for supraventricular tachycardia (SVT) in infants and children?

A. AV node reentry tachycardia

B. Orthodromic reciprocating tachycardia (antegrade over accessory pathway, retrograde over atrioventricular [AV] node)

C. Orthodromic reciprocating tachycardia (antegrade over AV node, retrograde over accessory pathway)

D. Wolff-Parkinson-White syndrome

Preferred response: C

Rationale

Orthodromic reciprocating tachycardia utilizes an accessory pathway as the retrograde limb, but Wolff-Parkinson-White syndrome may or may not be present in sinus rhythm, making response D incorrect.

3. Which statement is most true regarding adenosine?

A. Adenosine should never be administered in the presence of a wide QRS tachycardia.

B. Adenosine terminates most tachycardias by blocking conduction in accessory pathways.

C. Adenosine specifically blocks conduction in the AV node with little effect on blood pressure or sinus rate.

D. Prompt access to defibrillation should be readily available when administering adenosine.

Preferred response: D

Rationale

Adenosine can cause profound hemodynamic compromise or even ventricular fibrillation, requiring access to immediate defibrillation, especially if it is being administered to patients with wide QRS tachycardia or known Wolff-Parkinson-White syndrome.

4. What is the most appropriate acute therapy for incessant supraventricular tachycardias (SVTs) such as persistent junctional reciprocating tachycardia in an infant?
   A. Intravenous verapamil
   B. Procainamide infusion
   C. Repeated doses of adenosine until sinus rhythm is sustained
   D. Vagal maneuvers such as ice to face
   Preferred response: B

Rationale

The challenge in persons with incessant SVTs is the tendency for the SVTs to reinitiate. Measures directed at termination are of lesser utility. Repeated adenosine doses or repeated DC cardioversion may aggravate incessant behavior, and intravenous calcium channel blockers should not be administered to infants.

5. Regarding ventricular tachycardias (VTs), which of the following represents the most correct statement?
   A. Calcium channel blockers should never be administered for VT.
   B. Intravenously administered amiodarone is superior to intravenously administered lidocaine for treatment of sustained VT.
   C. The most appropriate acute therapy for polymorphic VT is intravenous magnesium.
   D. Unlike in adults, VTs in children are rarely life threatening.
   Preferred response: B

Rationale

Certain idiopathic forms of VT are seen in healthy young patients; these forms of VT may respond to calcium channel blockers acutely and are amenable to catheter ablation. However, all ventricular tachycardias should be approached initially as potentially life threatening, and for polymorphic VT (including torsades de pointes) or pulseless monomorphic VT, immediate cardioversion should precede intravenous drug therapy.

Chapter 36: Shock States

---

1. You are called to the emergency room to help evaluate two 3-year-old patients in separate rooms. The child in room A presents with a 3-day history of vomiting, diarrhea, and reduced eating and drinking. You find the child in room A to be

awake, alert, but fussy; the child has dry mucous membranes; heart rate, 146 beats per minute; blood pressure, 73/52 mm Hg; warm extremities; and capillary refill of 3 seconds. The child in room B presents with a similar history of 3 days of vomiting, diarrhea, and reduced intake. The child in room B is sleepy but able to be aroused. She becomes agitated when aroused and has dry mucous membranes; heart rate, 144 beats per minute; blood pressure, 74/46 mm Hg; cool extremities, and capillary refill of 3 seconds. Your assessment is that one of these children is hypovolemic, and the other is in compensated hypovolemic shock. Therefore what is your recommendation?

A. Both child A and B should be treated with oral rehydration over the next 24 to 48 hours per WHO guidelines.

B. Both child A and B should be treated with 20 mL/kg of crystalloid delivered intravenously in ≤15 min.

C. Child A should be treated with 20 mL/kg of crystalloid delivered intravenously in ≤15 min, and child B should be treated with oral rehydration over the next 24 to 48 hours per WHO guidelines.

D. Child A should be treated with oral rehydration over the next 24 to 48 hours per WHO guidelines, and child B should be treated with 20 mL/kg of crystalloid delivered intravenously in ≤15 min.

Preferred response: D

Rationale

Child A has hypovolemia due to gastroenteritis. Child A has normal compensatory responses without evidence of end-organ dysfunction. Child B has an abnormal neurologic exam and a widening pulse pressure. Child B is in compensated hypovolemic shock. Compensated shock should be initially treated with rapid volume administration, whereas patients with hypovolemia can be safely treated with oral rehydration per WHO recommendations.

2. A 5-year-old child with acute lymphoblastic leukemia and neutropenia presents to the pediatric intensive care unit with evidence of septic shock. Data suggest that children who receive <40 mL/kg of intravenous fluids and are still in shock at the end of the first hour have worse outcomes than those who receive >40 mL/kg and are still in shock at the end of the first hour. Therefore what is your goal?

A. Obtain a $ScvO_2$ from the indwelling central catheter, place an arterial line and obtain a serum lactate, and then titrate fluid resuscitation until you see the $ScvO_2$ and lactate improve to normal ranges.

B. Treat with 20 mL/kg of crystalloid in ≤15 min, and then reevaluate for evidence of fluid response.

C. Treat with 60 mL/kg of crystalloid fluid resuscitation within the first hour.

D. Treat with 60 mL/kg of crystalloid and colloid as indicated within the first hour.

Preferred response: B

Rationale

Although data suggest that early, rapid fluid resuscitation improves mortality, there

are accumulating data that suggest that fluid overload worsens mortality. Therefore the goal in fluid resuscitation is to give just what the patient requires. If the patient shows evidence of sustained response to fluid administration and resolution of shock, no further fluid boluses should be administered. If the patient shows refractory shock, fluid resuscitation should be continued for up to a total of 60 mL/kg in the first hour. After the first hour, if there is evidence of sustained shock, careful evaluation should be used to determine the indication for vasoactive/inotropic support with or without further fluid resuscitation.

3. You are working in the CICU and you receive a phone call from an outside provider in an emergency department caring for a 17-day-old newborn who weighs 3.2 kg and presented in shock. The patient is a full-term infant born to a G2P2 female who did not receive prenatal care. The patient was born at home and delivered by a midwife. Delivery was uncomplicated. The mother reports poor feeding for the last 24 hours, and this morning the newborn was found to be less responsive. In the ED, the patient presents with the following vital signs: temperature, 36.7°C; heart rate, 185 beats per minute; blood pressure, 52/28 mm Hg; respiratory rate, 74 per minute. The patient appears gray and is unresponsive. What do you recommend?
   A. Ceftriaxone, 20 mL/kg intravenous bolus of crystalloid, and transfer to the PICU
   B. Orotracheal intubation, ceftriaxone, 20 mL/kg intravenous bolus of crystalloid, and transfer to the PICU
   C. Orotracheal intubation, ampicillin and gentamicin, 10 mL/kg intravenous bolus of crystalloid, continuous infusion of prostaglandin E_1, and transfer to the PICU
   D. Orotracheal intubation, ampicillin and gentamicin, 10 mL/kg intravenous bolus of crystalloid, echocardiogram, and transfer to the PICU

   Preferred response: C

Rationale

Newborns (<28 days) presenting in shock should be suspected for sepsis and a ductal-dependent congenital heart disease. Therefore fluid resuscitation should be provided, but it should start with a lower volume and then be reevaluated for responsiveness. Ceftriaxone may be okay for newborns, but risks in the newborn period make ampicillin and gentamicin a better empiric choice. Empirically starting a continuous infusion of prostaglandin E_1 (PGE_1) at 0.05 to 0.1 mcg/kg/min may be lifesaving and should be started prior to obtaining the echocardiogram. PGE_1 may cause apnea, but in an unresponsive infant presenting in shock, early intubation is indicated.

Chapter 37: Pediatric Cardiopulmonary Bypass

---

1. When blood comes into contact with the cardiopulmonary bypass circuitry, these foreign surfaces will *not* do which of the following?

A. Activate inflammatory response

B. Cause hemolysis

C. Disrupt hemostasis

D. Shift the oxyhemoglobin curve leftward

Preferred response: D

Rationale

It is well documented that nonendothelial blood contact activates the systemic inflammatory response and causes hemolysis and coagulopathy. Oxyhemoglobin shifts are caused by changes in blood pH, temperature, pCO_2, and 2,3-DPG.

2. Which of the following is an effective strategy to protect the immature myocardium during ischemic arrest?

A. Increase the cardiac membrane resting potential.

B. Keep the myocardium warm.

C. Perfuse the coronaries with a hypotonic solution.

D. Prevent intracellular calcium accumulation.

Preferred response: D

Rationale

Calcium shifting at the cellular membrane is an energy-dependent process, and minimizing intracellular calcium accumulation will help to prevent ATP depletion. Decreasing the cardiac membrane resting potential to achieve diastolic arrest is the goal of depolarizing cardioplegia. Delivering a cold cardioplegia solution will minimize metabolic demands and prolong the myocardial tolerance to ischemia. An isotonic or hypertonic cardioplegia solution is desired to reduce intracellular water accumulation and edema.

Chapter 38: Critical Care After Surgery for Congenital Cardiac Disease

---

1. A 6-day-old child is returned to the cardiac intensive care unit after a stage I palliation (Norwood procedure) for hypoplastic left heart syndrome. He remains endotracheally intubated and has an open sternum. Heart rate is 180 beats/min and blood pressure is 55/28 mm Hg while on epinephrine (0.05 μg/kg/min) and milrinone (0.5 μg/kg/min). He is being ventilated with a tidal volume of 8 mL/kg, PEEP of 5 cm H_2O, rate of 26 breaths/min, and FiO_2 of 0.4. An arterial blood gas analysis shows severe metabolic acidosis (pH 7.16, $PaCO_2$ 40 mm Hg, PaO_2 78 mm Hg, SaO_2 94%, base deficit, 13). What is the next best step to manage this condition?

A. Decrease the FiO_2 to 0.21.

B. Decrease the milrinone dose to 0.3 μg/kg/min.

C. Increase the epinephrine dose to 0.08 μg/kg/min.

D. Increase the respiratory rate to 30 breaths/min.

Preferred response: A

Rationale

The patient has classic signs of an unbalanced circulation following the Norwood procedure, with excess pulmonary blood flow and decreased systemic perfusion (high Qp:Qs). This is a serious emergency and requires prompt action. Decreasing the FiO_2 to room air can be accomplished rapidly and will help balance the Qp:Qs. In some cases, carbon dioxide may need to be added to the inspired gas or subatmospheric FiO_2 to help reduce excessive pulmonary blood flow.

Decreasing the dose of milrinone would not be a reasonable strategy for this patient, who can in fact benefit from additional afterload reduction to increase systemic blood flow and help balance the Qp:Qs. For the same reason, increasing the dose of epinephrine could be detrimental as it will likely increase the systemic vascular resistance and increase pulmonary blood flow. Increasing the respiratory rate to 30 breaths/min would lower the $PaCO_2$, and although this will help compensate the acidosis, it will also lower pulmonary vascular resistance and adversely contribute to the already increased pulmonary blood flow.

2. A 6-month-old child with history of tricuspid atresia returns to the cardiac intensive care unit intubated following a bidirectional Glenn anastomosis. She is hemodynamically stable and in sinus rhythm but has significant hypoxemia (SaO_2 of 65%) despite being offered a FiO_2 of 1.0 through the ventilator. The hypoxemia persists despite adequate sedation and intravascular volume expansion with packed red blood cells to increase the hematocrit to 40%. Of the following, which intervention is least likely to meaningfully improve the arterial oxygen saturation in this patient?

A. Controlled hypoventilation (permissive hypercapnia)

B. Head elevation (30 degrees)

C. Inhaled nitric oxide

D. Intravenous milrinone and epinephrine

Preferred response: C

Rationale

Following the bidirectional Glenn anastomosis, arterial oxygen saturation should be in the 80% to 85% range; however, stabilization to this level can take a number of days. Persistent hypoxemia (SaO_2 <70%) can be secondary to a low cardiac output state (low SvO_2), low pulmonary blood flow, or lung disease. Treatment is directed at improving contractility, increasing superior vena cava venous return, reducing afterload, and ensuring the patient has a normal rhythm and hematocrit. Increased pulmonary vascular resistance is an uncommon cause, and inhaled nitric oxide (NO)

is not generally beneficial in these patients. This finding is not surprising because pulmonary artery (PA) pressure and resistance and vascular tone are not high enough following this surgery to see a demonstrable benefit from NO. Controlled hypoventilation targeting hypercapnia promotes increased cerebral blood flow and, consequently, increased blood flow through the superior vena cava (SVC)-PA anastomosis. Persistent profound hypoxemia should be investigated in the catheterization laboratory to evaluate hemodynamics, look for residual anatomic defects limiting pulmonary flow, such as SVC or PA stenosis or a restrictive atrial septal defect (ASD), and coil any significant venous decompressing collaterals (eg, azygous vein), if present.

3. Following a Fontan operation for palliation of the hypoplastic left heart syndrome, which of the following postoperative strategies is commonly used?
   A. Early extubation whenever the patient is able to assume spontaneous breathing
   B. Forced diuresis to lower the central venous pressure
   C. High doses of dopamine and epinephrine to increase systemic vascular resistance and blood pressure
   D. Mechanical ventilation with high levels of positive end-expiratory pressure to optimize lung inflation and increase pulmonary blood flow

   Preferred response: A

Rationale

Following a Fontan operation, liberation from positive pressure ventilation should be accomplished as soon as the patient is able to assume spontaneous breathing, provided there is no significant lung disease or atelectasis. For this reason, prolonged sedation and paralysis generally are not indicated. High doses of vasoactive drugs should be avoided because they increase the afterload to the systemic right ventricle. Lowering the central venous pressure is not indicated because pulmonary blood flow is largely dependent on systemic venous return. A high level of positive end-expiratory pressure should be avoided in these patients because it increases intrathoracic pressure, reduces venous return, and consequently reduces pulmonary blood flow.

4. Which of the following is true for a patient with tetralogy of Fallot?
   A. A residual ventricular septal defect (VSD) promotes left-to-right shunt and augments pulmonary blood flow.
   B. Epinephrine is the drug of choice in the postoperative period because it increases cardiac output and contractility of the poorly compliant right ventricle.
   C. Patients usually require high right atrial pressure postoperatively because of the hypertrophic and poorly compliant right ventricle.
   D. The presence of an atrial level communication is undesirable because it can lead to hypoxemia and decreased preload to the left ventricle.

   Preferred response: C

Rationale

The poorly compliant right ventricle requires high right-sided filling pressures (right atrial pressure). Use of vasodilators should be avoided during a hypercyanotic spell, because lowering systemic vascular resistance will increase the right-to-left shunt and worsen hypoxemia and acidosis. An atrial level communication is highly desirable in patients with significant right ventricular diastolic dysfunction, because it allows for a right-to-left atrial level shunt that ensures adequate left ventricular preload (although it causes arterial oxygen desaturation). Milrinone is the drug of choice in the postoperative period because of its lusitropic effects. A residual ventricular septal defect (VSD) is deleterious, particularly in the setting of a persistent right ventricular outflow tract obstruction.

Chapter 39: Cardiac Transplantation

---

1. Which of the following is the major cause of death in adolescents after heart transplant?

   A. Dysrhythmia

   B. Noncompliance

   C. Renal failure

   D. Thromboembolism

   Preferred response: B

Rationale

Currently the major cause of death in the adolescent heart transplant recipient is noncompliance with the medical regimen.

2. Which of the following is the preferred anticoagulant for patients in the intensive care unit who have myocardial dysfunction and are awaiting a heart transplant?

   A. Aspirin

   B. Coumadin

   C. Heparin

   D. Lovenox

   Preferred response: C

Rationale

All patients waiting for heart transplantation should be managed with systemic anticoagulation. Heparin is preferred, but warfarin is acceptable in a stable patient who is receiving inotropic support. We add a word of caution regarding the use of low-molecular-weight heparin for prophylaxis: Enoxaparin cannot be easily reversed in a patient who must go to the operating room emergently because a donor heart has been identified; cardiovascular surgeons prefer using heparin for prophylactic anticoagulation.

3. Which of the following is the first-line medication for management of hypotension in the potential heart donor?

   A. Dobutamine

B. Dopamine

C. Epinephrine

D. Vasopressin

Preferred response: D

Rationale

A catecholamine surge causing unnatural circulatory physiology that rapidly evolves is associated with brain death, making management of the donor difficult. This intense sympathomimetic outflow initially causes vasoconstriction resulting in tachycardia, hypertension, and increased myocardial oxygen demand. The result can be a direct injury to the myocardium in the potentially transplantable heart. Myocardial structural damage that includes myocytolysis, contraction band necrosis, subendocardial hemorrhage, edema formation, and interstitial mononuclear infiltration is seen. This initial sympathetic outflow is followed by a loss of sympathetic tone, resulting in marked vasodilatation and hypotension. The hypotension and cardiovascular collapse are related to decreased systemic vascular resistance rather than primary myocardial dysfunction. Vasopressin is now the first-line blood pressure support medication because it treats diabetes insipidus in addition to supporting blood pressure. Vasopressin infusion of less than 2.5 units/hour usually is sufficient to increase mean arterial blood pressure and not cause end-organ injury.

4. Cardiac output in the heart immediately after transplantation is impaired primarily by which of the following?

A. Arch obstruction

B. Diastolic dysfunction

C. Mitral valve insufficiency

D. Tricuspid valve insufficiency

Preferred response: B

Rationale

The major changes in the physiology of the transplanted heart are related to autonomic denervation, including diastolic dysfunction and an exaggerated response to exogenously administered catecholamines. The transplanted heart also must adapt to a new environment related to the recipient's lung function and elevated pulmonary vascular resistance (PVR). Hemodynamics of the transplanted heart will reflect a significant shift to the left of the pressure-volume curve. Diastolic dysfunction can be demonstrated from the early transplant period. Diastolic dysfunction is a significant impairment to early allograft function, limiting cardiac output. Diastolic dysfunction emphasizes the importance of heart rate and early sinus node function. The capability of temporary pacing in the early perioperative period is mandatory.

5. Which of the following is associated with increased perioperative mortality for heart transplantation?

A. Mitral valve insufficiency

B. Tricuspid valve insufficiency

C. Pulmonary arterial pressure <15 mm Hg

D. Pulmonary vascular resistance (PVR) >6 Wood units

Preferred response: D

Rationale

High PVR in the recipient increases perioperative morbidity and mortality and can affect late survival. All potential heart recipients undergo cardiac catheterization prior to heart transplantation to document the anatomy of systemic and pulmonary venous connections, determine pulmonary artery size and distribution, and calculate PVR. The upper limit of PVR associated with successful orthotopic heart transplantation is not known. Criteria developed from the adult heart transplant experience indicate that a PVR greater than 6 Wood units or a transpulmonary gradient (pulmonary artery mean pressure–left atrial mean pressure) greater than 15 mm Hg is associated with increased perioperative mortality. The transpulmonary gradient is the most useful number for estimating PVR because measurement of cardiac output in the catheterization laboratory can be flawed. In children the PVR index, which is determined by dividing the transpulmonary gradient by the cardiac index, is more useful because children come in all sizes. A PVR index of less than 6 index units is associated with low perioperative mortality.

6. Hyperglycemia following heart transplantation is most likely related to which of the following?

A. Antithymocyte globulin

B. Basiliximab

C. Furosemide

D. Tacrolimus

Preferred response: D

Rationale

Hyperglycemia is common after heart transplantation with tacrolimus-based immune suppression. The combination of decreased insulin production from islet cells caused by tacrolimus and decreased peripheral utilization related to high-dose corticosteroids results in nonketotic hyperglycemia. Insulin is initially mandatory in management but often can be discontinued if the tacrolimus dose is reduced and the corticosteroid portion of maintenance immune suppression is discontinued.

7. Diastolic dysfunction in a patient after heart transplantation most commonly will manifest as which of these changes following a normal saline solution fluid challenge?

   A. An increase in right atrial pressure by 2 mm Hg

   B. An increase in left atrial pressure by 2 mm Hg

   C. No change in right atrial pressure

   D. No change in stroke volume

   Preferred response: B

Rationale

Hypotension and cardiovascular collapse in patients after heart transplantation are related to decreased systemic vascular resistance rather than primary myocardial dysfunction. Large fluid volumes and high-dose inotropic agents at α-adrenergic dosing range are administered, causing volume overload and vasoconstriction that can injure all donor organs. Hearts that are supported on high-dose inotropic agents likely will exhibit myocardial injury. A risk factor that predicts donor heart failure is a history of high-dose dopamine, dobutamine greater than 20 μg/kg/min, and epinephrine greater than 0.1 μg/kg/min.

8. Effects of nesiritide include which of the following?

   A. Decreased afterload

   B. Direct inotropic effect

   C. Increased renin

   D. Tachycardia

   Preferred response: A

Rationale

Nesiritide, a recombinant B-type natriuretic peptide, is now approved for treatment of acutely decompensated heart failure. Endogenous B-type natriuretic peptide is a cardiac hormone produced by the failing heart, and nesiritide is identical to the naturally occurring peptide. Nesiritide reduces preload and afterload, leading to increases in cardiac output/index without reflex tachycardia or direct inotropic effect. In addition, this drug promotes natriuresis and diuresis and suppresses the renin-angiotensin axis and endogenous catecholamines.

9. A 5-year-old child with dilated cardiomyopathy in your pediatric intensive care unit is waiting for an orthotopic heart transplant. The child's weight is 20 kg. She

is receiving intermittent noninvasive continuous positive airway pressure. Her mixed venous oxygen saturation is 45%, and her left ventricular ejection fraction (LVEF) is less than 20%. Inotropic support includes a milrinone drip of 0.75 μg/kg/min and an epinephrine drip of 0.02 μg/kg/min. A donor organ becomes available within 1 hour of flying time from your medical center. The donor is a teenager who became brain dead after a motor vehicle accident 3 days ago. The donor weight is 40 kg. Resuscitation at the accident site was required with unknown down time. Vasopressin and epinephrine were initiated and given for the first 24 hours but subsequently weaned to low-dose dopamine. Current evaluation of the donor heart shows an LVEF of 60% with trivial mitral valve regurgitation. Would you recover this donor heart for your patient?

A. No; the uncertain down time and high-dose inotropic support make the donor unacceptable.

B. No; the donor is too large for my patient.

C. No; the distance from the center makes it impossible for ischemic time to be less than 4 hours.

D. Possibly; the donor is potentially acceptable. I would review all of the information from the donor site.

Preferred response: D

Rationale

Donor heart availability is limited, and the number of patients who die while waiting for a heart transplant is significant. Your recipient is critically ill, and the need for circulatory support is imminent (via extracorporeal membrane oxygenation or a ventricular support device), so all potential donor hearts should be critically evaluated. An estimate of donor "downtime" is important but often inaccurate. Inotropic resuscitation of the donor is common. The use of high-dose inotropic support (ie, epinephrine and norepinephrine) for a prolonged period of time (>24 hours) reflects significant donor heart ischemia, and in such cases the donor heart should not be used for transplantation. A donor/recipient weight of greater than 2 : 1 is common. We use the donor/recipient aortic root size rather than weight to estimate the size mismatch. We rarely use an undersized donor (ie, weight less than 20% of the recipient) for transplantation. Flight time from the transplant center is relative. Ideally a total ischemic time of less than 4 hours is ideal (ie, the time from aortic cross-clamp at the donor site to release of the aortic cross-clamp on the recipient). It is important to remember that a perfect heart to transplant is never available. We encourage direct verbal communication with the donor referral center.

10. A 15-year-old patient with tricuspid atresia has had palliative surgery (atrial to pulmonary connection) (Fontan). A myopathic ventricular dysfunction and protein-losing enteropathy have developed. He has just had an orthotopic transplant. You are discussing potential immune suppression regimens. Pretransplant panel reactive antibody is 10% for class 1 human leukocyte antigens. What immune suppression regimen should you select?

A. ATG (antithymocyte globulin) induction, tacrolimus, azathioprine, and prednisone for maintenance

B. ATG induction, maintenance cyclosporine, and prednisone

C. ATG induction, maintenance tacrolimus, mycophenolate, and prednisone

D. ATG induction, maintenance sirolimus, azathioprine, and prednisone

Preferred response: C

Rationale

Options are available for both induction and maintenance immune suppression in children after heart transplantation. If induction immune suppression is selected, ATG, a pan-lympholytic agent that has been used effectively for more than 25 years, is used. IL-2 receptor blockade also has been shown to be effective for induction. We prefer to use induction when there is human leukocyte antigen antibody sensitization of the recipient. Mycophenolate is preferred rather than azathioprine because the gastrointestinal adverse effects are minimized. Prednisone has been a standard part of "triple drug immune suppression regimens," but some centers have reported equivalent effectiveness of corticosteroid-free regimens. Sirolimus is the only drug contraindicated early after transplant because of the delayed effect on wound healing.

11. An 8-year-old girl with restrictive cardiomyopathy is being evaluated for transplant. A hemodynamic study is performed as part of the pretransplant evaluation. Hemodynamics are as follows: blood pressure, 110/80 mm Hg; pulmonary artery, 62/40 mm Hg, mean 50 mm Hg; pulmonary artery wedge, 35 mm Hg; left ventricular end-diastolic pressure, 35 mm Hg; and cardiac index, 2.5 L/min/m^2. What is your decision regarding this patient's suitability for orthotopic heart transplant?

A. Before making a decision, hemodynamics should be repeated with a fraction of inspired oxygen of 1.0 and nitric oxide.

B. Listing the patient for a heart transplant should be delayed until medical management of pulmonary hypertension can be initiated.

C. The patient is a candidate for heart and lung transplant only.

D. The patient is a candidate for orthotopic heart transplant with a recognized increased risk factor of elevated pulmonary vascular resistance (PVR).

Preferred response: D

Rationale

The evaluation of PVR in the potential heart transplant recipient is a critical part of the evaluation. The right ventricle of the donor heart will acutely fail if it is exposed to excessive afterload from pulmonary vascular disease of the recipient. A pretransplant hemodynamic assessment with conditions favoring pulmonary vasodilation using oxygen, nitric oxide, and or nitroprusside is necessary to determine if the recipient is an orthotopic heart transplant candidate alone or will need to be referred for a heart and lung transplant. A transpulmonary gradient (pulmonary artery mean pressure–left atrial pressure) of less than 15 mm Hg or an estimated PVR index of less than 4 to 6 units/m^2 is an acceptable level of PVR for orthotopic heart transplantation.

Chapter 40: Acute and Chronic Heart Failure

1. A full-term 3-month-old male with new onset heart failure is admitted to the pediatric intensive care unit. His oxygen saturation is 85% in room air, you hear a loud holosystolic murmur at the apex, a CXR reveals bilateral haziness, and an EKG demonstrates Q waves in lead aVL. What is the most important next step in managing this patient?

   A. Administer a continuous infusion of furosemide.

   B. Initiate epinephrine.

   C. Perform cardiac catheterization.

   D. Perform endotracheal intubation.

   Preferred response: D

Rationale

This patient is most likely presenting with acute heart failure secondary to anomalous left coronary artery from the pulmonary artery (ALCAPA), giving a characteristic Q wave pattern in avL and a murmur of mitral insufficiency. Endotracheal intubation is an important next step to reduce the afterload of the heart. Epinephrine may result in increased afterload and worsened cardiac output, although low doses may be useful if cardiac contractility is impaired. An IVF bolus is inappropriate, as this will worsen pulmonary edema. Cardiac catheterization is indicated to confirm the diagnosis in anticipation of operative repair; however, the patient must first be stabilized. A furosemide infusion may assist with symptomatic management of the patient and is therefore a useful adjunctive therapy, but the most important next step for this patient is endotracheal intubation.

2. A 13-year-old female who initially presented with recent flulike symptoms as well as progressive fatigue, shortness of breath, and exercise intolerance has been endotracheally intubated due to hypoxemia and is currently on maximal ventilator settings. A bedside echocardiogram shows a dilated heart with mild bilateral atrioventricular (AV) valve insufficiency and a left ventricular ejection fraction (LVEF) of 18%. She is currently on milrinone and dopamine infusions with poor peripheral perfusion and decreased urine output. What is the next step in her management?

   A. Administer intravenous immunoglobulin (IVIG).

   B. Discuss ECMO cannulation with the surgical service.

   C. Perform cardiac catheterization for endomyocardial biopsy.

   D. Wean PEEP to reduce barotrauma and promote venous return.

   Preferred response: B

Rationale

As this patient is currently on maximum medical therapy with evidence of persistent end-organ dysfunction, it is time to discuss ECMO cannulation with the surgical service. IVIG may be indicated, as this presentation is suspicious for myocarditis, as is an endomyocardial biopsy for confirmation of the diagnosis; however, the patient's hemodynamic state must first be stabilized. Reducing PEEP will increase cardiac afterload and worsen the patient's current status. Once she has been cannulated onto ECMO, her ventilator settings may be temporarily lowered to allow for recovery prior to attempted weaning.

Chapter 41: Physiologic Foundations of Cardiopulmonary Resuscitation

1. What is the major pharmacologic effect of epinephrine during cardiopulmonary resuscitation?

   A. It raises aortic systolic pressure.

   B. It raises aortic diastolic pressure.

   C. It raises the heart rate via its β-agonist actions.

   D. It improves cardiac compliance by relaxing myocardium during diastole.

   Preferred response: B

Rationale

At resuscitative doses of epinephrine, the α-adrenergic receptor effect predominates, increasing systemic vascular resistance in addition to increasing cardiac output. The α-adrenergic–mediated vasoconstriction of epinephrine increases aortic diastolic pressure and thus coronary perfusion pressure, a critical determinant of successful resuscitation.

At nonresuscitative doses, epinephrine has potent β_1-adrenergic receptor activity and moderate β_2- and α_1-adrenergic receptor effects. Clinically, low doses of epinephrine increase cardiac output because of the β_1-adrenergic receptor inotropic and chronotropic effects, whereas the α-adrenergic receptor–induced vasoconstriction is often offset by the β_2-adrenergic receptor vasodilation. The result is an increased cardiac output, with decreased systemic vascular resistance and variable effects on the mean arterial pressure.

2. Compared with monophasic defibrillators, which of the following is true about biphasic defibrillators?

   A. They are too expensive and have an unacceptable fault rate.

   B. They have been shown to burn too much myocardium in smaller children.

   C. They require less energy output to be effective.

   D. They should be used at one-fourth the starting dose in children.

   Preferred response: C

Rationale

Defibrillators can deliver energy in a variety of waveforms that are broadly characterized as monophasic or biphasic. Biphasic waveforms defibrillate more effectively and at lower energies than do monophasic waveforms. The value of higher energy biphasic shocks was demonstrated in the BIPHASIC trial.[1]

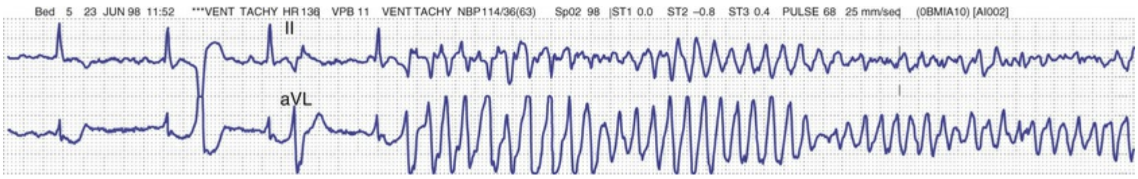
3. A 16-year-old female with a history of chronic medications, including metoclopramide, ondansetron, and erythromycin, presents conscious with the tracing shown below: Which of the following antiarrhythmic agents would be most appropriate in the acute setting?

   A. Adenosine

   B. Amiodarone

   C. Lidocaine

   D. Procainamide



Preferred response: C

Rationale

Due to her medication profile, this patient is at risk for acquired long QT syndrome (LQTS); this tracing represents torsades de pointes (TdP). TdP is a form of polymorphic ventricular tachycardia that occurs in the setting of either acquired or congenital LQTS, where it appears as though the QRS is twisting around an isoelectric al axis. Delay in treatment can cause the rhythm to degenerate into ventricular fibrillation. The first-line treatment for TdP is IV magnesium, which is effective in both treatment and prevention of TdP. It is effective even in the setting of a normal serum magnesium level. Of the antiarrhythmics presented, lidocaine would be the most appropriate choice in the acute management of TdP, as it shortens the duration of the action potential. Both amiodarone and procainamide prolong the QT interval, which worsens the pathophysiology of this arrhythmia. Adenosine is used primarily to diagnose and treat supraventricular tachycardias. It would not treat TdP. In the setting of an unstable patient, ventricular defibrillation would be the first-line therapy.

Reference

1. Stiell IG, Walker RG, Nesbitt LP, et al. BIPHASIC Trial: a randomized comparison of fixed lower versus escalating higher energy levels for defibrillation in out-of-hospital cardiac arrest. *Circulation*. 2007;115:1511.

Chapter 42: Performance of

Cardiopulmonary Resuscitation in Infants and Children

1. A healthy 12-year-old is playing baseball and is hit in the center of the chest by a pitch. He suddenly collapses and loses consciousness, is unresponsive to stimulation, and has an occasional gasp (agonal) breath. When paramedics arrive, what is the *first* ECG rhythm they are likely to see?

   A. Asystole

   B. Pulseless electrical activity

   C. Sinus bradycardia

   D. Ventricular fibrillation

   Preferred response: D

Rationale

Following a sharp blow to the chest with sudden collapse, called commotion cordis, the most common cause of arrest is an R on T phenomenon leading to ventricular fibrillation. If an automated external defibrillator (AED) had been applied prior to EMS arrival, a shock would have been advised.

2. A 12-year-old with severe asthma has respiratory distress unresponsive to albuterol aerosols and oxygen. The child becomes confused, then unconscious and unresponsive. The SpO_2 was 90%, then 70%, and is not picking up. No pulse is palpable, and the arterial catheter tracing is flat (nonpulsatile) on the monitor. The child has an occasional gasp (agonal) breath. Which ECG rhythm on the monitor is *most likely*?

   A. Pulseless electrical activity

   B. Sinus bradycardia

   C. Ventricular fibrillation

   D. Ventricular tachycardia

   Preferred response: A

Rationale

This child has progressive respiratory failure due to lower airway obstruction (asthma) with severe arterial desaturation, and this has progressed to a pulseless rhythm, with evidence of no perfusion and no pulse (by palpation or arterial line). This is most likely pulseless electrical activity. One should review the H's and T's for potential causes of PEA, with a high suspicion for pneumothorax in a severe asthmatic.

3. During cardiopulmonary resuscitation (CPR), which of the following bedside monitoring tools is most predictive of a return of spontaneous circulation (ROSC)?

   A. Exhaled CO_2 capnograph of >15 torr

B. Femoral pulse palpable with chest compressions

C. Pacer spikes visible on electrocardiogram when transcutaneous pacing is initiated

D. Pulse oximeter waveform detected with chest compressions

Preferred response: A

Rationale

During the low-flow phase of CPR, achieving optimal cardiac output/coronary perfusion pressure is consistently associated with an improved chance of the return of spontaneous circulation. Bedside capnography can be useful as a rough estimate of pulmonary blood flow. Achieving an optimal exhaled carbon dioxide concentration >15 torr has been associated with improved short-term outcome in both animal and human studies.

4. A previously healthy 7-year-old boy under evaluation for syncope suddenly collapses. His cardiac arrest rhythm looks like ventricular fibrillation (VF) on the monitor. If high-quality standard CPR were provided (with chest compressions and 100% fraction of inspired oxygen rescue breathing), what would an arterial blood gas (ABG) and a venous blood gas (VBG) drawn just prior to defibrillation most likely show?

   A. ABG: pH 7.10, PCO_2 65, PO_2 300 VBG: pH 7.35, PCO_2 65, PO_2 40

   B. ABG: pH 7.10, PCO_2 55, PO_2 50 VBG: pH 7.10, PCO_2 55, PO_2 50

   C. ABG: pH 7.05, PCO_2 25, PO_2 20 VBG: pH 7.25, PCO_2 55, PO_2 35

   D. ABG: pH 7.30, PCO_2 30, PO_2 300 VBG: pH 7.10, PCO_2 75, PO_2 30

   Preferred response: D

Rationale

Provision of high-quality CPR (ie, push hard, push fast but not too fast, allow full chest recoil, minimize interruptions, and do not overventilate) can result in cardiac output that approaches 50% of normal. The other choices have either inappropriately low PO_2 levels given this scenario or a venous pH that is higher than the one recorded from the corresponding ABG.

Chapter 43: Structure and Development of the Upper Respiratory System in Infants and Children

---

1. What is narrowest part of the upper airway in infants?

   A. Larynx

B. Nasal valve

C. Nasopharynx

D. Subglottis

Preferred response: B

Rationale

The structure of the upper airway differs in the infant, young child, and young adult. Preferential nasal breathing is present in neonates and persists until 6 months of age because of the high-riding larynx in the neck with the soft palate and vallecula in close anatomic approximation. The nasal tip—in particular, the nasal valve area—is the area of highest resistance in the upper airway of the infant.

2. A pediatric patient requires intubation. Laryngoscopy shows an easy grade 1 view; however, the age-appropriate endotracheal tube is difficult to pass. Which is *not* a possible reason for this to happen?

A. Laryngeal web

B. Subglottic stenosis

C. Tracheal stenosis

D. Tracheomalacia

Preferred response: D

Rationale

Tracheomalacia would not obstruct passing of the endotracheal tube because it is weakness or external compression of the trachea. It may hinder ventilation but the endotracheal tube should be able to pass easily.

3. What method can be used to reach a definitive diagnosis of a laryngeal cleft?

A. Fiberoptic endoscopic examination of swallowing (FEES)

B. Flexible nasopharyngoscopy

C. Operative endoscopy with palpation of the larynx

D. Videofluoroscopic swallow study (VFSS)

Preferred response: C

Rationale

To assess for a laryngeal cleft, palpation of the interarytenoid area is the gold standard.

Chapter 44: Structure and Development of the Lower Respiratory System in Infants and Children

1. A baby is born at 24 weeks' gestation and has a difficult respiratory course in the NICU. She eventually gets a tracheostomy for chronic ventilation and is transferred to the PICU at 6 months of age. Her oxygen requirement has been decreasing, and she is discharged home on a ventilator. Which of the following is a correct statement regarding the development of this child's lower respiratory system?
   A. Alveolarization is complete in this child.
   B. The acinus is the gas exchange area of the lung.
   C. The pulmonary veins course with the airways and the bronchioles throughout the lung.
   D. Type I alveolar epithelial cells produce and secrete surfactant.
   Preferred response: B

Rationale

Surfactant is produced by type II cells, not type I cells. Gas exchange occurs in the acinus. Alveolarization appears to be nearly complete at about age 2 years and so should continue to occur in this child. The pulmonary veins do not normally course with the airways and bronchioles. When they do, this suggests alveolar-capillary dysplasia.

2. The primary role of the lung is gas exchange. What structural feature of the lung supports this function?
   A. Alveolar macrophages are scarce in the normal lung.
   B. The connective tissue space, or interstitium of the lung at the alveolar level, has abundant lymphatics.
   C. The internal surface area of the adult lung is 70 to 80 m^2, of which 90% covers the pulmonary capillaries
   D. When fully matured the pulmonary artery and its thickness is approximately 90% that of the aorta.
   Preferred response: C

Rationale

- The internal surface area of the adult lung is 70 to 80 m^2, of which 90% covers the pulmonary capillaries; thus the air-blood surface available for gas exchange is 60 to 70 m^2.
- When fully matured, the pulmonary artery and its thickness is only about 60% that of the aorta.
- Alveolar macrophages are abundant and form an important arm of the defense mechanism of the lung.
- The connective tissue space, or interstitium of the lung at the alveolar level, does not have lymphatics, but it can accumulate fluid that can be absorbed into the lymphatic system, which ends usually at the respiratory bronchiolar level.

3. Which of the following is the most predominant bronchial mucosal cell type?
   A. Basal cells
   B. Brush cells
   C. Ciliated cells
   D. Neuroendocrine cells
   Preferred response: C

Rationale

The bronchial mucosa contains several epithelial cell types: ciliated, mucus producing (goblet cells), basal, brush, and neuroendocrine. Ciliated cells constitute more than 90% of the epithelial cell population in the conducting airways, but the proportion and number of cilia per cell decrease from the proximal to the distal airways. In addition to its ciliary beating movement, the ciliated columnar cells regulate the depth of the composition of the periciliary fluid and transport ions across the epithelium. The basal cell has a progenitor cell role and also functions to maintain adherence of columnar cells to the basement membrane. The brush cell, thought to have a role in fluid absorption or chemoreceptor function, is found rarely in the tracheobronchial and alveolar epithelia. Although mucous goblet cells secrete mucin, it is the submucosal glands that produce more than 90% of the mucus needed for mucociliary function.

Neuroendocrine cells can be solitary near the basal lamina between columnar cells or in collections called neuroepithelial bodies that occur near branch points of bronchi. A number of neural markers are expressed (eg, 5-hydroxytryptamine, chromogranin A, neuron-specific enolase, and synaptophysin), and a number of hormones are produced (eg, endothelin, calcitonin, and bombesin [gastrin-releasing peptide]). They are more abundant in the fetus and likely have a role in lung growth or maturation.

4. It is not known with certainty when alveolar development is completed. However, based on our current knowledge, we believe which of the following statements?
   A. All alveoli are present at birth.
   B. All alveoli are present at 16 weeks' gestation.
   C. Alveoli continue to develop until 2 to 8 years of age.
   D. Alveoli continue to develop into adulthood.
   Preferred response: C

Rationale

At birth, primitive alveoli called saccules are evident, but approximately 50 million alveoli are already formed. The number of alveoli in a normal adult can vary from 300 to 500 million, and they have a diameter of 150 to 200 μm. The early work by Dunnell suggesting that new alveolar formation ceased at about age 8 years has been challenged by Thurlbeck, who has shown that alveolarization appears to be nearly complete at about age 2 years. Lung volume correlates with body size, but alveolar surface area correlates with metabolic activity; thus alveoli become more complex in shape during maturation and as increasing O_2 is required.

Chapter 45: Physiology of the Respiratory System

1. Regarding respiratory physiology, which one of the following statements is *least* accurate?
   A. Peripheral airway resistance in children <5 years is fourfold higher than in older children and adults.
   B. Specific compliance is the same for adults and children, but specific conductance is higher in children.
   C. With laminar flow, resistance to flow is proportional to viscosity.
   D. With turbulent flow, resistance to flow is proportional to density.
   Preferred response: B

Rationale

Compliance is a measure of the elastic nature of the chest wall and lungs. In children, due to decreased development of the structure of the lungs and developing calcification of the ribs, the compliance of both the lungs and chest wall is decreased.

2. Which one of the following clinical conditions is not expected to be associated with sudden decline in end-tidal CO_2 as it relates to the alveolar gas equation?
   A. Air embolism
   B. Cardiac standstill
   C. Hypoventilation
   D. Obstruction of the endotracheal tube
   Preferred response: C

Rationale

The volume of air entering the lungs each minute that actually participates in gas exchange is called the alveolar ventilation (A). It is therefore the difference between the total volume of air entering the lungs each minute (minute ventilation, E) and the volume of air entering the lungs that does not participate in gas exchange (dead space: D): A = E – D. Anything decreasing the amount of CO_2 seen by the end-tidal sensor will decrease the level displayed, but a sudden decrease represents a sudden change, whereas hypoventilation would demonstrate a gradual decrease.

3. Lack of oxygen equilibration due to diffusion limitation (*alveolar-capillary block*) can be evaluated by measuring which of the following?
   A. Diffusing capacity of CO (carbon monoxide)
   B. Diffusing capacity of CO_2 (carbon dioxide)
   C. Distribution of an inhaled gas mixture containing a radioactive marker
   D. FEV-1/VC when inhaling pure oxygen

Preferred response: A

Rationale

DCO is a good index of the diffusion capacity of oxygen (DO_2).

4. Reduction of the pulmonary diffusing (D) capacity to one-fourth of its normal value would be expected to have what effect on systemic arterial oxygen and carbon dioxide partial pressures (compared to normal)?
   A. Decrease PaO_2 and decrease $PaCO_2$
   B. Decrease PaO_2 but no change in $PaCO_2$
   C. Increase PaO_2 and decrease $PaCO_2$
   D. Increase PaO_2 and increase $PaCO_2$
   Preferred response: B

Rationale

PaO_2 decreases when the diffusion capacity of oxygen (DO_2) decreases to less than one-third its normal value. But DCO_2 is so high normally that even a decrease to one-fourth will still permit carbon dioxide to equilibrate in the time that blood passes through pulmonary capillaries.

Chapter 46: Noninvasive Respiratory Monitoring and Assessment of Gas Exchange

---

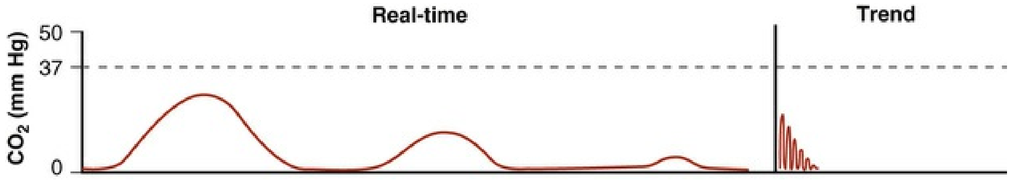
1. Which of the following does not influence pulse oximetry measurement?
   A. Ambient light
   B. Dyshemoglobinopathies
   C. Hypothermia
   D. Jaundice
   Preferred response: D

Rationale

Low peripheral perfusion states such as hypothermia and motion artifact are the most common causes of inaccurate pulse oximetry readings. Other sources of error include interfering dyes or other pigments in the blood and ambient light. Intravenous dyes and certain colors of nail polish may falsely lower pulse oximetry readings. The presence of dyshemoglobinopathies is an infrequent clinical problem but can result in erroneous pulse oximetry readings. Abnormal hemoglobin levels (carboxyhemoglobin, methemoglobin) that have similar absorbance spectra can lead to overestimation of the true Sao_2. Jaundice, anemia, and skin tone or color do not

typically affect pulse oximetry measurement.

2. Which of the following clinical scenarios best explains this capnography waveform?



A. Airway obstruction
B. Apnea
C. Esophageal intubation
D. Hypoventilation
Preferred response: C

Rationale

Incorrect placement of the endotracheal tube in the esophagus results in initial detection of trace $PetCO_2$, which is not sustained over time, and an uncharacteristic waveform that lacks a defined respiratory upstroke, plateau, or inspiratory downstroke. Hypoventilation may be indicated by a gradual rise of $PetCO_2$, whereas airway obstruction is demonstrated by a change in the shape of the capnography waveform (absence of expiratory or alveolar plateau). Sudden loss of $PetCO_2$ with a waveform that transitions from normal to flat line is an indication of laryngospasm or apnea.

3. A standard pulse oximeter is able to detect:

A. Oxygenated hemoglobin only
B. Oxygenated and deoxygenated hemoglobin
C. Methemoglobin
D. Carboxyhemoglobin
Preferred response: B

Rationale

Pulse oximetry is based on the observation that the attenuation of light passing through blood-perfused tissue changes with pulsation of blood and that the alternating component of the light attenuation results from the composition of arterial blood. Hemoglobin has characteristic light-absorbing properties that change with oxygen binding. The deoxy form of hemoglobin (deoxyHb) has a single peak in the visible and near-infrared region. Oxyhemoglobin (oxyHb) has two peaks in the visible region but no significant peak in the near-infrared region. At any given wavelength, there is a difference in absorption between oxyHb and deoxyHb except where the spectra cross, at wavelengths called *isosbestic wavelengths*, where the

absorption is the same for each state. At non-isosbestic wavelengths, the difference in absorption can be used to determine the fraction of oxyhemoglobin. Saturation of hemoglobin is defined as follows:

$$Hb_{sat} = [oxyHb]/([oxyHb]+[deoxyHb]),$$

where Hb_{sat} = fractional saturation of hemoglobin, [oxyHb] = concentration of oxyhemoglobin, and [deoxyHb] = concentration of deoxyhemoglobin. Hemoglobin percent saturation, as commonly reported, is determined by multiplying Hb_{sat} by 100.

4. Which of the following are the most reliable sites for monitoring rapidly changing core temperature?

A. Distal esophagus, tympanic membrane, pulmonary artery, and nasopharynx

B. Distal esophagus, pulmonary artery, bladder, and rectum

C. Skin, bladder, and rectum

D. Skin, bladder, and nasopharynx

Preferred response: A

Rationale

Commonly used core temperature monitoring sites include the distal esophagus, tympanic membrane, pulmonary artery, and nasopharynx. These sites detect core temperature changes rapidly, in contrast to urinary bladder or rectal measurements, which are good reflections of core temperature during steady-state conditions. Cutaneous temperature monitoring is the least reliable indicator of rapid core temperature changes. However, monitoring peripheral temperatures can be useful in defining core peripheral gradients in temperature and assist in tracking vasoconstriction and vasodilation. Oral probes are used as thermometers, and some have been attached to pacifiers. A thermometer that scans the temporal artery is also available. The ideal spot for continuous core temperature monitoring is a pulmonary artery catheter, but because of the invasive nature of this monitor, it would never be placed for temperature monitoring alone.

An esophageal temperature probe positioned in the lower third of the esophagus is a good alternative. In this position, the temperature sensor is immediately behind the left atrium and accurately tracks core temperature without significant time lag in the majority of situations. If a gastric tube with applied suction is present next to the temperature probe, it must be on the low intermittent setting or the temperature readings will be falsely lowered. Nasopharyngeal and tympanic membrane temperatures are good indicators of cerebral temperature but can be inaccurate as a result of sensor positioning. Axillary and peripheral skin probably are the most convenient sites for monitoring temperatures, but they also are the most inaccurate because of skin perfusion.

Chapter 47: Overview of Breathing

Failure

1. What is the primary mechanism by which shock causes respiratory failure?
   A. Cortical brain ischemia
   B. Inadequate muscle blood flow
   C. Metabolic acidosis
   D. Overstimulation of medullary respiratory centers
   Preferred response: B

Rationale

In shock, blood flow to respiratory muscles becomes inadequate for aerobic muscle work. Respiratory muscles first develop an oxygen debt and then lose their ability to contract. Metabolic acidosis stimulates chemoreceptors and brain stem respiratory sites, causing tachypnea and dyspnea, but not preventing muscle work. The high respiratory muscle workload of respiratory failure does increase muscle blood flow to the extent supportable by the circulation and is a strain on the heart, but it is not the cause of respiratory failure in shock. Cortical brain ischemia might impair volitional responses to respiratory distress, but it is the brain stem that governs automatic responses to respiratory stimuli. Overstimulation of medullary respiratory centers may drive tachypnea but is not the cause of respiratory muscle failure from shock.

2. A child fell while rock climbing and suffered injury to his thoracic spinal cord at the level of T6. He has lower extremity flaccidity and a sensory level at the lower sternum and at the level of T6 posteriorly. What would be the greatest impact of this injury on breathing?
   A. Dependence on accessory muscles of respiration
   B. Diminished strength of cough
   C. Loss of the cough reflex
   D. Reduced inspiratory capacity
   Preferred response: B

Rationale

The muscles of the abdomen are used for active expiration and are innervated by the lower thoracic spinal cord. They are important for coughing, sneezing, and for forced expiration, but play little role in passive expiration. The cough reflex involves abdominal muscles as well as deep intercostals, which are innervated by both upper and lower thoracic motor neurons. The reflex would be intact despite a T6 injury, but the cough itself would be weak. Inspiration is powered by the superficial and parasternal intercostal muscles and by the accessory muscles of respiration, so inspiratory capacity should be preserved. Dependence on accessory muscles for normal inspiratory power should not be necessary. Retractions reflect inspiratory effort, which should not be directly altered by this injury.

3. Which of the following is a true statement about control of breathing?
   A. Aortic and carotid chemoreceptors directly modulate respiratory drive.
   B. Brain stem respiratory control is located in a single medullary nucleus.
   C. Volitional and automatic control of breathing may be independently impaired.
   D. Volitional control of breathing requires medullary modulation.
   Preferred response: C

Rationale

Volitional control of respiration normally may be asserted in the awake state, but only up to a point. One cannot consciously hold the breath beyond a certain level of medullary stimulation. Supratentorial injury may impair volitional control of breathing but spare automatic control. On the other hand, medullary stroke may impair automatic control of breathing but leave volitional control intact.

Brain stem respiratory control is widely distributed in the pons and medulla and involves numerous other brain stem nuclei. All mechanoreceptor and chemoreceptor input that modulates respiratory drive must be processed in the brain before effector responses can occur. Aortic and carotid chemoreceptors modulate breathing only after integration in the medulla. Patients with loss of all cortical behavior may exhibit respiratory distress and use accessory muscles of breathing.

4. Which of the following is a true statement about respiratory muscle exhaustion?
   A. Myoglobin provides adequate oxygen reserves to protect against respiratory muscle exhaustion from hypoxemia.
   B. Muscle training can prevent fatigue of respiratory muscles.
   C. Rapid shallow breathing is a sign of respiratory muscle exhaustion.
   D. Shock may precipitate respiratory muscle exhaustion and respiratory arrest.
   Preferred response: D

Rationale

Shock can diminish oxygen supply to the respiratory muscles and precipitate muscle exhaustion. Respiratory arrest is a final common pathway to death in all forms of untreated shock.

Hypoxemia also can cause respiratory muscle exhaustion. Although myoglobin may provide a short-term buffer to transient oxygen deficits, it cannot prevent persistent hypoxia or blood flow limitation from progressing to respiratory muscle exhaustion. Krebs cycle production of adenosine triphosphate is very inefficient. Most Krebs cycle adenosine triphosphate is generated by oxidation of Krebs cycle reducing fragments. When there is insufficient oxygen to feed oxidative phosphorylation, reducing fragments build up and inhibit Krebs cycle enzymes. Anaerobic metabolism cannot prevent respiratory muscle exhaustion. Muscle training improves the ability of respiratory muscles to meet excessive demand, although only to a point. Rapid shallow breathing is a compensatory mechanism to deal with elevated work of breathing and occurs before respiratory muscles become exhausted.

5. Which of the following values is the least likely to stimulate the peripheral or

central chemoreceptors, resulting in an increase in respiratory rate?

A. Low hemoglobin

B. $PaCO_2$

C. PaO_2

D. pH

Preferred response: A

Rationale

Hypoxemia is a powerful stimulus to ventilation mediated by sensory input originating in the carotid body chemoreceptor. Peripheral chemoreceptor activity (reflected in minute ventilation) increases slightly with decrements in PaO_2 below 500 mm Hg and rises steeply as PaO_2 falls below 50 mm Hg. Low oxygen tension, rather than low oxygen content, is the important ventilator stimulus. Little carotid body response results from profound anemia. Carotid chemoreceptor response also contributes to arousal from sleep during episodes of hypoxia. Hydrogen ion concentration and carbon dioxide tension independently activate chemoreceptors in the carotid body and in the brain stem. The simultaneous presence of hypoxia augments the hypercapnic ventilatory response.

Chapter 48: Ventilation/Perfusion Inequality

1. Shunt fraction can be calculated. Which of the following data would be required?

A. Arterial oxygen content, alveolar-arterial oxygen difference, cardiac output

B. Arterial oxygen content, venous oxygen content, assumption of oxygen content of blood undergoing gas exchange

C. Cardiac output, arterial oxygen saturation, and oxygen consumption

D. Dead space fraction, minute ventilation, and cardiac output

Preferred response: B

Rationale

The equation for calculating the shunt fraction is based on the Fick equation

$$Q_s/Q_t = \frac{C_cO_2 - C_aO_2}{C_cO_2 - C_vO_2}$$

where Q_s and Q_t represent shunt and total pulmonary blood flow, respectively and CaO_2, CvO_2, and CcO_2 are the arterial, venous, and pulmonary capillary oxygen contents, respectively. The dead space fraction can be derived from measurement of mixed end-tidal CO_2 and arterial PCO_2 but is not needed for calculation of shunt

fraction. Minute ventilation also is not needed for the calculation of the shunt fraction, but total cardiac output is part of the equation as seen above. A similar equation employing carbon dioxide contents in place of oxygen contents could be constructed.

Although cardiac output is derived in the calculation of shunt fraction, response C is incomplete as the equation also requires contents. Alveolar ventilation and barometric pressure are not required for the calculation. Response A has only one of the necessary variables for the equation. Establishment of a significant shunt fraction will inform the clinician that there will be decreased alveolar-arterial oxygen difference locally.

2. Regarding the effect of intrapleural pressures and alveolar size, which of the following statements is accurate?
   A. The intrapleural pressure at the apex is more negative than at the base, so the alveoli are larger at the apex.
   B. The intrapleural pressure at the apex is more positive than at the base, so alveoli are smaller at the apex.
   C. The intrapleural pressures do not vary between the apex of the lung and the base and therefore do not affect alveolar size.
   D. The intrapleural pressure at the base is more positive than at the apex, so alveoli are larger at the base.

   Preferred response: A

Rationale

The lung is a viscoelastic structure encased in the supporting chest wall with gravity imposing a globular shape on the lung. Pleural pressure is more negative at the apex of the lung compared with the base, increasing approximately 0.25 cm H_2O per centimeter of vertical distance toward the lung base. Thus transpulmonary pressure is more marked at the apex so apical alveoli are large and at the upper end of the normal pressure-volume curve. They distend less for a given pressure change, that is, they are less compliant. In the spontaneously breathing upright human, maximal gas distribution occurs at the base and progressively diminishes toward the lung apex. This gradient also exists when inhalation occurs in the supine or lateral decubitus position, although to a lesser degree.

3. The correct statement regarding alveolar size and compliance in different lung regions in a healthy child in the upright position is:
   A. Apical alveoli are larger and therefore more compliant than alveoli at the base of the lungs.
   B. Alveolar size is the same at the apex and the base of the lungs, so compliance is equal.
   C. Alveoli at the base of the lungs are larger and therefore more compliant than apical alveoli.
   D. Alveoli at the base of the lungs are smaller and therefore more compliant than apical alveoli.

   Preferred response: D

Rationale

Apical alveoli are large and at the upper end of the normal pressure-volume curve. They distend less for a given pressure change, that is, they are less compliant. Alveoli at the base are smaller and more compliant than apical alveoli.

4. What is the definition of time constant?
   A. The time required to inflate 63% of final lung volume and is equal to the product of resistance and compliance
   B. The time required to inflate 95% of final lung volume and is equal to the product of resistance and compliance
   C. The time required to inflate 63% of final lung volume and is equal to resistance/compliance
   D. The time required to deflate 95% of final lung volume and is equal to resistance/compliance

   Preferred response: A

Rationale

The time constant (the product of resistance and compliance) is defined as the time required for inflation to 63% of final lung volume, inflation being indefinitely prolonged. Therefore a given lung unit with a slow time constant will fill more slowly than one with a fast time constant and also will empty more slowly. Should the time constants of different lung units vary, as frequently happens in pulmonary illness, gas distribution will be determined in part by the rate, duration, and frequency of inhalation.

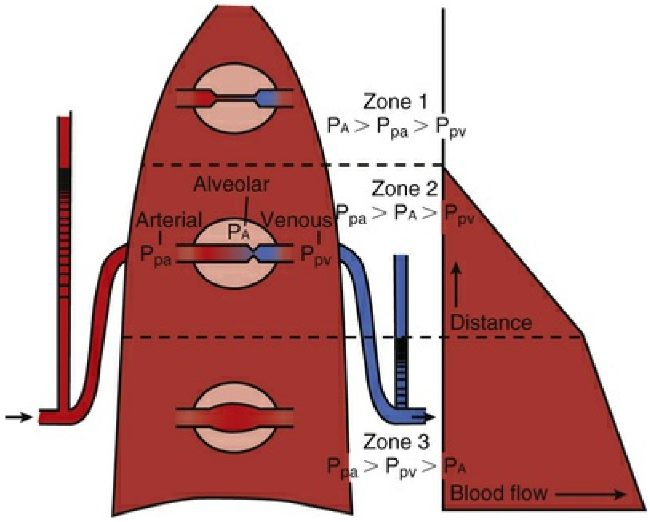
5. In an upright individual with normal lung perfusion, which West zone represents a region where $P_A > P_{PV} > P_{PA}$, where P_A is alveolar pressure, P_{PA} is pulmonary artery pressure, and P_{PV} is pulmonary venous pressure?
   A. Zone I
   B. Zone II
   C. Zone III
   D. This representation does not exist

   Preferred response: D

Rationale

The three-zone model of pulmonary blood flow has been widely used to explain the heterogeneity of perfusion within the lung (Fig. Q48.5). Three variables comprise the components of this model: pulmonary arterial (P_{PA}), alveolar (P_A), and pulmonary venous (P_V) pressures. The degree of blood flow within the lung depends on the relative magnitudes of these pressures within that zone. Zone 1 ($P_A > P_{PA} > P_V$) has negligible blood flow, because the higher alveolar pressure is believed to compress collapsible capillaries. This region is one of minimal gas exchange and "wasted" ventilation. Zone 1 conditions are rare except in cases of diminished pulmonary blood flow (eg, hypotension and cardiac failure) or increased P_A encountered during

positive pressure ventilation. Zone 2 consists of the mid portions of the lungs in which $P_{PA} > P_A > P_V$, where flow rate is determined by the difference between pulmonary arterial and alveolar pressure. Venous pressure does not influence the flow rate. Blood flow progressively increases with descent through this zone, because P_{PA} increases whereas P_A remains relatively constant.



In the lowest zone of the lung described by West, zone 3, $P_{PA} > P_V > P_A$, therefore the arteriovenous pressure gradient (P_{PA}-P_V) determines flow rate. This gradient remains relatively constant descending through this zone, although because pleural pressures increase less, blood flow is greater in more dependent areas of zone 3. A zone 4 region in the most dependent areas of lung also has been described. In this region, transudated pulmonary interstitial fluid increases interstitial pressures, thereby reducing blood flow; this effect is exaggerated as lung volume diminishes from total lung capacity to residual volume.

6. Which West zone represents a region where $P_{PA} > P_A > P_V$, where P_A is alveolar pressure, P_{PA} is pulmonary artery pressure, and P_{PV} is pulmonary venous pressure?

   A. Zone I

   B. Zone II

   C. Zone III

   D. This representation does not exist

   Preferred response: B

Rationale

See the rationale for question 4.

7. Hypoxemia in acute respiratory distress syndrome (ARDS) is primarily due to which of the following pathophysiologic mechanisms?

   A. Diffusion impairment

B. Increased dead space

C. Intrapulmonary shunt

D. Oxygen toxicity

Preferred response: C

Rationale

The large intrapulmonary shunt accounts for the hypoxemia of ARDS that is unresponsive to increases in inspired oxygen. The shunt results from alveolar flooding, atelectasis, and right-to-left shunt through a patent foramen ovale. The low V_A/Q units explain the increase in venous admixture with decreasing inspired fractional concentration of oxygen and may represent transient events with alveoli in the process of collapsing or reexpanding. Units with low V_A/Q deteriorate to shunt as a result of absorption atelectasis, especially when exposed to high levels of inspired O_2. Diffusion impairment does contribute substantially to the gas exchange abnormalities in patients with ARDS.

8. A 7-year-old child with status asthmaticus is undergoing treatment in your pediatric intensive care unit with systemic corticosteroids, β_2-agonists, ipratropium, and 0.60 fraction of inspired oxygen. She has moderate air entry, bilateral wheezes, no nasal flaring, and mild intercostal retractions. Her respiratory rate is 22 per minute. Her pulse oximetry saturations prior to and after initiation of therapy were 91% and 86%, respectively. Which of the following is the most likely explanation for this observed change in oxygen saturation?

A. Excessive fatigue with hypoventilation and resultant hypoxemia

B. Increase in airway secretion due to the institution of ipratropium

C. Increase in ventilation/perfusion mismatch due to β_2-agonist

D. Mucus plugging of the airways due to institution of ipratropium

Preferred response: C

Rationale

In persons with asthma, high inspired oxygen concentrations may prevent hypoxic pulmonary vasoconstriction and place low alveolar ventilation (V_A)/perfusion (Q) regions at risk for absorption atelectasis, and high doses of bronchodilators may enhance the perfusion of low V_A/Q areas, exacerbating V_A/Q mismatch. However, the beneficial effects of bronchodilators on airway resistance generally outweigh the worsening in V_A/Q mismatch.

This child is not showing signs of excessive fatigue. There is no nasal flaring, and retractions are only mild. The air entry is moderate and wheezes are present, therefore response A is not correct. Ipratropium is an anticholinergic that causes a decrease in airway secretion (thus response B is incorrect), and there are no clinical signs that this child has a mucus plug in her airway (thus response D is incorrect).

9. One of the proposed mechanisms for improvement in oxygenation in patients with acute respiratory distress syndrome (ARDS) placed in the prone position is:

A. Perfusion is greater in the nondependent areas in the prone position.

B. Perfusion is greater in the dependent areas in the prone position.

C. Ventilation is greater in the dependent areas in the prone position.

D. Ventilation is lower in the nondependent areas in the prone position.

Preferred response: A

Rationale

In ARDS and other lung injury models, nonaerated or poorly aerated portions of the lung are found mainly in the dependent areas. Perfusion is largely gravity-independent, especially in West zone 3 conditions. The majority of perfusion goes through dorsal lung regions, whether in the prone or supine position. Consequently, perfusion is greatest to the dependent lung in the supine position and to the nondependent lung in the prone position. Positive pressure, especially positive end-expiratory pressure, redistributes perfusion toward the dependent portion of the lungs by creating the condition of West zones 2 and 1. This redistribution may increase the vertical perfusion gradient in the supine position but may reduce it in the prone position. These various physiologic factors contribute to the increase in the uniformity of perfusion in the prone position.

10. You are caring for a 4-month-old child with bronchiolitis who has developed respiratory failure. You instruct the medical student rotating on your service that bronchiolitis has features of both restrictive and obstructive lung diseases. Common pulmonary abnormalities that occur in both restrictive as well as obstructive lung diseases are:

A. Altered closing capacity especially with respect to functional residual capacity (FRC).

B. Increased intrapulmonary shunt fraction

C. Increased time constants

D. Increased zone 3 pulmonary blood flow conditions

Preferred Response: A

Rationale

In almost all lung diseases alterations in closing capacity and functions residual capacity (FRC) occur resulting in altered gas exchange. Obstructive lung diseases (e.g., asthma) are characterized by increases in FRC and TLC whereas in restrictive lung diseases (e.g. ARDS) both capacities are decreased. However, closing capacity changes as well and so in asthma there is increased V_A/Q mismatch whereas in ARDS there is increased intrapulmonary shunt. Many other lung diseases result in V_A/Q mismatch or increased intrapulmonary shunt, and some of these diseases are discussed further in the chapter. Increased alveolar-capillary diffusion time is seen in diseases that result in abnormalities of the alveolar-capillary interface, such as pulmonary fibrosis, and is not a defining feature of either obstructive or restrictive lung diseases. The time constant of lung segments is defined by the equation

$$\tau = R \times C$$

where the time constant (τ) is the product of resistance (R) and compliance (C) or R divided by elastance (E), the inverse of compliance. In general the time constant is increased in obstructive lung diseases and decreased in restrictive lung disease. However, lung diseases tend to be inhomogeneous and so some local areas may have time constants that differ markedly from the lung as a whole. This is especially true in bronchiolitis. Finally, zone 3 in the West model of pulmonary blood flow occurs when pulmonary arterial and venous pressures exceed pulmonary alveolar pressures. In obstructive lung disease, airways become hyperinflated, increasing alveolar pressure, and this will likely diminish the amount of zone 3 areas. Similarly, in restrictive diseases, there is loss of lung volume or pulmonary edema that increases the amount of zone 4 regions.

11. A 7-month-old girl with severe pneumococcal pneumonia develops respiratory failure requiring intubation of her trachea and institution of mechanical ventilation. Shortly after intubation an arterial blood gas shows the following results: pH 7.32, $paCO_2$ 36 mm Hg, paO_2 57 mm Hg on and FiO_2 of 0.6. Her pulse oximeter reads 88%. Explanation for differences in the abnormalities seen in the levels of carbon dioxide and oxygen include:

   A. Carbon dioxide has greater diffusion in blood than oxygen does.

   B. The difference is entirely explained by the alveolar gas equation.

   C. The greater density of CO_2 results in better gas exchange in gravitationally dependent areas of the lung.

   D. The hemoglobin-oxygen binding curve has limited influence on blood CO_2 levels.

   Preferred Response: E

Rationale

Carbon dioxide does have greater density than oxygen and does diffuse more readily than oxygen. However, neither of these features of carbon dioxide would explain the differences in levels of oxygen and carbon dioxide in this patient with pneumonia. In patients with diffusion abnormalities (e.g., pulmonary fibrosis), especially in states of increased cardiac output, pulmonary capillary blood will equilibrate with the CO_2 in alveolar gas but equilibrium may not be reached with the oxygen in alveolar gas. Still, pneumonia is not distinguished by decreased diffusion capacity. In patients with gas intrapulmonary shunt or V_A/Q mismatch abnormalities the carbon dioxide levels in affected pulmonary capillary units will be elevated, but often this can be corrected by increases in alveolar minute ventilation. In more normal areas the CO_2 in the pulmonary capillary blood is below normal and corrects the high CO_2 of these areas when the blood mixes in the large pulmonary veins and this probably is the case for this infant. In contrast, since the majority of oxygen in the blood is carried by hemoglobin, areas of abnormal gas exchange are characterized by pulmonary capillary blood that is not fully saturated. This cannot be corrected by less diseased areas of the lung because the small amount of dissolved oxygen in areas that are more normal will not improve the PO_2 enough to bring the saturations of arterial blood to normal levels.

Chapter 49: Mechanical Dysfunction of the Respiratory System

1. A child with advanced cirrhosis is admitted to the ICU for management of acute gastrointestinal bleeding. The child has severe ascites and has become progressively more obtunded and hypoxemic. Which of the following mechanisms is most likely to result in a negative cardiovascular response to the institution of positive pressure ventilation in this patient?

   A. A disproportionate increase in pleural pressure as lung volume increases

   B. An increased need for sedation after endotracheal intubation

   C. A negative effect of PEEP on left ventricular contractility

   D. A reduction in lung compliance after the addition of PEEP

   Preferred response: A

Rationale

Abdominal distention decreases chest wall compliance and, as a result, pleural pressure increases markedly as the lungs expand, decreasing venous return.

2. Which of the following statements describes most accurately the relationship between the pressure displayed by the ventilator (measured at the endotracheal tube connector) and alveolar pressure during volume-controlled (constant flow) and pressure-controlled (decelerating inspiratory flow) mechanical ventilation?

   A. The difference between ventilator pressure and alveolar pressure is determined by lung compliance in both modes.

   B. The difference between ventilator pressure and alveolar pressure is not affected by air leaks around the endotracheal tube during pressure-controlled ventilation.

   C. Ventilator pressure is higher than alveolar pressure at end-inspiration during volume-controlled ventilation.

   D. Ventilator pressure is higher than alveolar pressure at end-inspiration during pressure-controlled ventilation.

   Preferred response: D

Rationale

During volume-controlled ventilation, inspiratory flow continues throughout inspiration. Consequently, at the end of inspiration, there is a gradient of pressure between the endotracheal tube connector and the alveoli. During pressure-controlled ventilation, flow decreases and ultimately ceases during inspiration. Thus the two pressures tend to equilibrate at the end of inspiration.

3. Which of the following conditions is most likely to increase the volume displacement of the diaphragm in a spontaneously breathing infant?

A. Abdominal distention

B. Croup

C. Pulmonary edema

D. Spinal cord section at the level of C8

Preferred response: D

Rationale

Intercostal muscle paralysis causes severe rib cage distortion during inspiration, adding to the volume that the diaphragm has to displace during a breath. All the other conditions tend to decrease tidal volume.

4. Regarding transmural pressures of thorax (PTH), lung (PL), and chest wall (PW), which of the following is correct (PA = alveolar pressure, Pb = atmospheric pressure, and Ppl = pressure at pleural surface)?

A. PL = PA – Pb

B. PL = PA – Ppl

C. PTH = Ppl – Pb

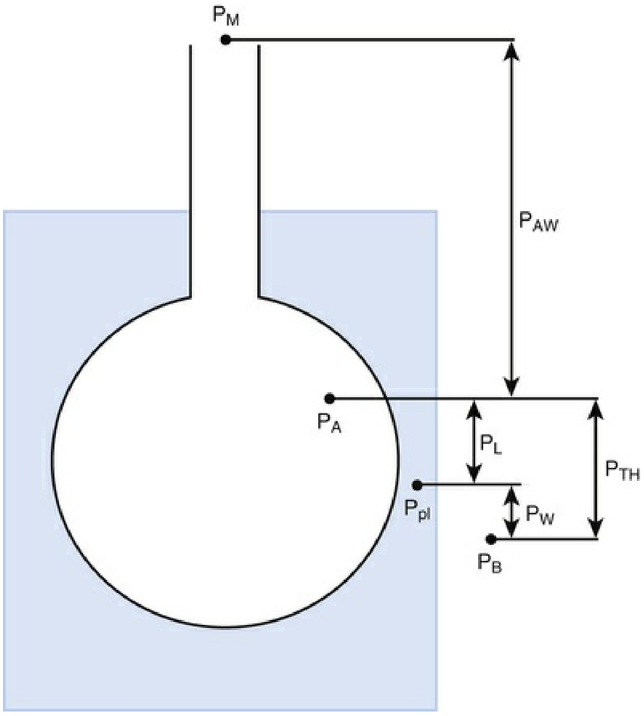
D. PW = PA – Ppl

Preferred response: B

Rationale

Different pressures are needed to inflate the thorax, the lungs, and the chest wall. When the respiratory muscles are completely relaxed, the thorax, the lungs, and the chest wall are all held at their respective volumes by outward-acting pressure gradients across their walls. These pressure gradients or transmural pressures are defined by the following equations:

$$
\begin{aligned}
PTH &= PA - Pb \\
PL &= PA - Ppl \\
PW &= Ppl - Pb
\end{aligned}
$$

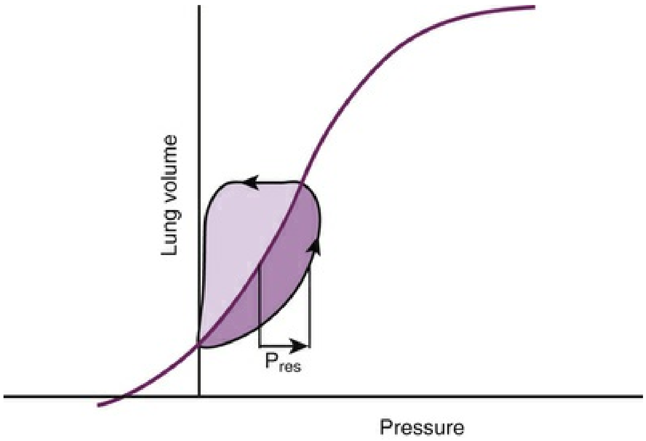


5. Which term is used to describe the property responsible for the development of pressure-volume loops of the respiratory system during breathing?
   A. Compliance
   B. Elastance
   C. Hysteresis
   D. Resistance
   Preferred response: C

Rationale

Analysis of the volume-pressure relationships of the thorax and its components becomes more complicated when pressure changes generated by gas flow and by the movement of the lung and chest wall tissue as the lungs inflate and deflate are considered. These pressure changes result from molecular interactions between the gas and the airway walls, within the gas stream itself, and among the components of the gas-liquid interface and the tissue.

These molecular interactions always result in a net loss or dissipation of energy from the respiratory system. The lost energy can no longer be used to perform work, and consequently dissipative pressure losses cause the volume-pressure relationships of the respiratory system to follow a different trajectory depending on the direction of the volume change. This property, known as *hysteresis,* is responsible for the development of loops when the volume-pressure relationships are plotted continuously during a breath. In this graphic representation, the dissipative pressures can be easily identified as the horizontal distance between the volume-pressure tracing and the corresponding point on the elastic volume-pressure relationship. The work done against these pressures can be quantified as the area enclosed by the loop.



6. Regarding elastic properties of the lung and chest wall, which of the following statements is correct?
   A. Elasticity is a dissipative property of the lungs and chest wall.
   B. Outward elastic recoil of the lungs is counterbalanced by the inward elastic recoil of the chest wall.
   C. The relaxation volume of the lungs in an adult is the residual volume.
   D. The negative pressure generated between the lung tissue and chest wall contributes to venous return at normal lung volumes.

   Preferred response: D

Rationale

Elasticity is typically a nondissipative process because the energy needed to produce elastic deformation during inspiration is accumulated in the tissues and then used to empty the lungs during expiration. In contrast, all resistive processes are dissipative: The energy liberated by the friction of the gas against the airway walls or by the molecular interactions within the tissue is transformed into heat and transported outside of the system by the blood or the expired gas.

Elastic pressures result from the tendency of the components of the lungs and chest wall to recover their original shape after undergoing deformation. By definition, elastic recoil drives the thorax and its individual components to adopt a volume, known as the *relaxation volume,* at which recoil itself is extinguished. The relaxation volumes of the lungs and the chest wall are the volumes that each of these components would adopt if all the mechanical constraints imposed by their mutual attachments and interactions were removed. The relaxation volume of the thorax, in contrast, is defined by the mechanical interaction of the lungs and the chest wall. It coincides with the point at which the opposing elastic recoils of these two components neutralize each other.

In the adult, the relaxation volume of the lungs is lower than the residual volume (the volume of gas contained in the lungs at the end of a forced expiration). The relaxation volume of the chest wall, by contrast, exceeds 50% of the vital capacity (the maximal volume of gas that can be inhaled from residual volume). This discrepancy in the relaxation volumes of the lungs and chest wall has three important consequences. First, it forces the relaxation volume of the thorax as a whole to occupy a position intermediately between the relaxation volumes of the

lungs and the chest wall (at approximately 35% of vital capacity). Under most circumstances, this volume coincides with the functional residual capacity (FRC), which is the volume contained in the lungs at the end of a tidal expiration. Second, as the thorax starts to rise above its relaxation volume during inspiration, the outward recoil of the chest wall contributes to the expansion of the lungs, thereby reducing the work that the respiratory muscles need to perform during normal circumstances. Finally, at normal breathing volumes, the opposing actions of the lungs and chest wall recoils create a negative pressure at the boundaries of the lung tissue with the chest wall and the other intrathoracic structures. This negative pressure is an important contributor to the return of venous blood to the chest.

In an infant, the chest wall generates remarkably little outward recoil within the normal range of breathing volumes. Because the inward recoil of the lungs varies little with respect to lung size and age during development, the relaxation volume of the infant's thorax is proportionally smaller than that of the adult. If, as occurs in the adult, the FRC coincided with this relaxation volume (15% of vital capacity compared with 35% in the adult), then the infant would be at a definite disadvantage in terms of alveolar stability and oxygenation. Newborns of most mammalian species have developed physiologic strategies to maintain their FRC above the relaxation volume of the thorax.

7. Maintenance of alveolar stability and oxygenation in neonates depend on physiologic strategies to do which of the following?

   A. Increase closing capacity

   B. Increase residual volume

   C. Increase vital capacity

   D. Maintain the FRC above the relaxation volume of the thorax

   Preferred response: B

Rationale

Newborns of most mammalian species have developed physiologic strategies to maintain their FRC above the relaxation volume of the thorax. These strategies are generally directed at interrupting expiratory flow before expiration is complete and include shortening of the expiratory time, contraction of adductor muscles of the glottis to retard exhalation, and persistence of the tonic activity of the inspiratory muscles during expiration.

8. Compared with adults and older children, premature infants and neonates are able to tolerate high lung volumes during mechanical ventilation without cardiovascular compromise, possibly because of which of the following conditions?

   A. Their lower airway resistance

   B. Their higher cardiac contractility

   C. Their higher cardiac output

   D. Their higher chest wall compliance

   Preferred response: D

Rationale

The pressure inside the pleural space is really determined by the elastic recoil of the chest wall and the volume of the thoracic contents. As long as lung volume is not forced above its normal range and chest wall compliance is unaltered by disease, pleural pressure (and thus the pressure around the major vessels and the heart) remains low, regardless of the airway pressures. Conversely, excessive lung distention (eg, in asthma) is always associated with a high pleural pressure and, for that reason, is less well tolerated from a cardiovascular point of view. The dependence of pleural pressure on chest wall compliance explains why premature infants and newborns, who have very large chest wall compliance, have limited changes in this pressure during positive pressure ventilation, even if physiologic lung volumes are exceeded. Disease-induced reductions in chest wall compliance, on the other hand, always increase pleural pressure and reduce venous return to the heart. This is one reason why patients with abdominal distention typically have low cardiac output and why relief of the distention (eg, by paracentesis in patients with ascites) reduces pleural pressure and increases cardiac output.

9. Which one of the following areas is considered the *zero reference* during inspiration?
   A. The alveoli
   B. The extrathoracic airway
   C. The intrapleural space
   D. The mouth
   Preferred response: D

Rationale

Airway transmural pressure varies during breathing. Its variations result from the fact that inspiration and expiration have very different effects on the pressures inside and outside the airways. The pressure inside all airways undergoes qualitatively similar changes during each phase of the breathing cycle. During inspiration, for instance, there is a gradient of increasingly negative pressures from the mouth, where pressure is atmospheric (or the zero reference), to the alveolar spaces, where the pressure must be negative (or subatmospheric) for gas to flow in. This negative pressure is of course driven by the actions of the respiratory muscles and transmitted to the lungs via the link between the chest wall and lungs at the pleural space. During expiration, alveolar pressure becomes positive and the gradient is inverted, with the pressures inside the airways being always positive but diminishing toward the mouth.

10. What happens to the extrathoracic and intrathoracic portion of the airways during a normal respiratory cycle of inspiration and expiration with airflow?
   A. During inspiration, the pressure surrounding the extrathoracic airway is more positive than the lumen, resulting in narrowing of the airway.
   B. During inspiration, the pressure surrounding the extrathoracic airway is more negative than the lumen, resulting in narrowing of the airway.
   C. During expiration, the pressure surrounding the intrathoracic airway is more

negative than the lumen, resulting in narrowing of the airway.

D. During expiration, the pressure surrounding the intrathoracic airway is more negative than the lumen, resulting in dilation of the airway.

Preferred response: A

Rationale

During inspiration, there is a gradient of increasingly negative pressures from the mouth (zero reference), where the pressure is atmospheric, distally to the airway. The pressure at the alveolar spaces must be negative (or subatmospheric) for air to flow. The pressure inside the airways is always negative, regardless of intra- or extrathoracic location.

During expiration, for air to move from the alveolar spaces to the mouth, the pressures must be more positive distally and decrease toward the mouth. Normal breathing changes in airway caliber depend on the location of the airway (intrathoracic versus extrathoracic) and the phase of the respiratory cycle (inspiration versus expiration).

Extrathoracic airways include the pharynx, larynx, and extrathoracic portion of the trachea and are surrounded by neck tissue, maintaining constant atmospheric pressure around these areas. During inspiration, the pressures distal to the extrathoracic airway become more negative, causing the extrathoracic portions of the airway to narrow. The opposite holds true for the intrathoracic airway. During inspiration, the pressure surrounding their walls (intrapleural pressure) becomes more negative compared with the pressure inside the lumen, which causes these portions of the airway to dilate.

To be correct, responses B through D should read as follows:

B. During inspiration, the pressure surrounding the extrathoracic airway is more *positive* than the lumen resulting in narrowing of the airway.

C. During expiration, the pressure surrounding the extrathoracic airway is less positive than the lumen, resulting in dilation of the airway.

D. During expiration, the pressure surrounding the intrathoracic airway is more positive than the lumen, resulting in narrowing of the airway.

11. What is the equal pressure point?

A. During inspiration, the point at which transmural pressure is positive

B. During inspiration, the point at which transmural pressure is negative

C. During expiration, the point at which the pleural pressure equals alveolar pressure

D. The pressure midway in the airway, where the pressure distal to the mouth equals the pressure proximal to the alveoli

Preferred response: C

Rationale

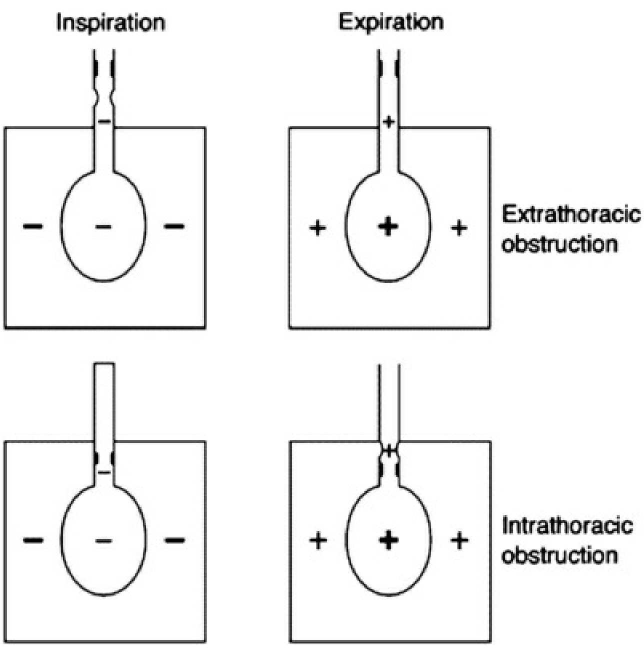
The narrowing of the intrathoracic airways during expiration is contingent on the existence of a pressure gradient from the alveoli to the mouth. Alveolar pressure (P_A) must always exceed pleural pressure (P_{pl}) by a magnitude equivalent to the elastic

recoil of the lungs. As the gas progresses downstream during expiration, frictional pressure losses lower the pressure inside the airways. Eventually the cumulative pressure losses can be as large as the pulmonary elastic recoil, and the pressure inside the airways becomes equal to P_{pl}. Beyond this *equal pressure point,* airway transmural pressure becomes negative (ie, the pressure outside exceeds the pressure inside the airway) and acts to collapse the airway.

12. Stridor in a child with croup occurs during which process?
   A. Expiration due to a more positive pressure downstream from the obstruction
   B. Expiration due to a more negative pressure downstream from the obstruction
   C. Inspiration due to a more negative pressure downstream from the obstruction
   D. Inspiration due to a more positive pressure downstream from the obstruction
   Preferred response: C

Rationale

When airway obstruction is extrathoracic (eg, with croup, glossoptosis, or tonsil or adenoid hypertrophy), the person must create a more negative pressure inside the airway segment downstream from the obstruction to overcome the increased resistance during inspiration. Therefore this segment of the airway tends to collapse, worsening the obstruction and producing a characteristic turbulent noise (inspiratory stridor) as gas accelerates through the narrowest point and induces vibrations in the airway mucosa, creating in the process a decrease in inside pressure that approximates the walls of the airway even further. The obstruction is relieved during expiration because the pressure inside the airway segment, now upstream from the obstruction, must become more positive with respect to atmospheric pressure to force gas flow through the obstruction.



13. When does wheezing in a child with tracheobronchial compression occur?

A. During inspiration and expiration due to a more positive pressure downstream from the obstruction

B. During expiration due to a less positive pressure downstream from the obstruction

C. During expiration due to a more positive pressure downstream from the obstruction

D. During inspiration due to a more positive pressure downstream from the obstruction

Preferred response: C

Rationale

When airway obstruction is intrathoracic (eg, with extrinsic compression of the trachea and bronchi, tracheobronchomalacia, and asthma), during inspiration, the pressure inside the airways downstream from the obstruction has to become more negative than that inside the airways upstream. However, no matter how negative, the pressure inside the airways still must be less negative than the pleural pressure because otherwise the lung recoil ($P_A - P_{pl}$) would be negative, which is unimaginable. Thus during inspiration the transmural pressure of intrathoracic airways remains positive. In contrast, during expiration the pressure inside the airway segment located between the obstruction and the thoracic outlet may become lower than the pleural pressure at some point. This situation, coupled with the convective acceleration of flow at the obstructed segments, causes these airways to collapse and produce high-pitched vibrations (wheezing), expiratory delay, and dynamic hyperinflation.

Chapter 50: Specific Diseases of the Respiratory System: Upper Airway

1. An 18-month-old boy arrives to the emergency department with sudden onset high fever, toxic appearance, stridor, and drooling. His oxygen saturation on blow-by oxygen supplementation is 96%. Lateral neck radiograph shows a “thumb sig.” What is the most appropriate next step in the treatment of his condition?

   A. Bedside nasal fiberoptic examination of the pharynx to confirm the diagnosis

   B. Conservative management with noninvasive ventilation and antibiotics

   C. Endotracheal intubation in the emergency room

   D. Transport to the operating room for intubation

   Preferred response: D

Rationale

This patient shows the classic signs and symptoms of epiglottitis. It is now a rare disease among vaccinated young children, but the sudden onset of severe airway obstruction requires prompt recognition and treatment. At the same time, care

should be taken not to disturb the patient, as agitation can result in complete airway obstruction. For this reason, fiberoptic examination of the epiglottis in the patient who is awake is usually not advisable. Similarly, attempts to examine the oropharynx directly or to start an intravenous line should be discouraged. If the patient will tolerate it, humidified oxygen should be administered, preferably through a plastic hose held by the parent.

If the suspicion for epiglottitis is high, the child should go to the operating room as quickly as possible. In the operating room, the patient is anesthetized with an inhaled anesthetic (sevoflurane) and oxygen while the patient is spontaneously breathing. Once the patient has been anesthetized, an intravenous catheter is inserted. Laryngoscopy is then performed. It may be exceedingly difficult to obtain a direct view of the glottis and trachea because of the large swollen epiglottis. Nevertheless, it is almost always possible to pass an endotracheal tube through the edematous tissues and into the trachea. Nasotracheal intubation is preferred to orotracheal intubation because the tube is more readily secured to the face, the patient cannot bite the tube, and salivation is decreased. An otolaryngologist should be in the operating room and ready to do an emergency tracheostomy if an airway cannot be secured by endotracheal intubation, although this is rarely necessary.

Endotracheal intubation is preferred to tracheostomy because it has been shown that complications are more common when a tracheostomy has been routinely used to treat epiglottitis.

After the airway is secured, blood cultures and cultures of the epiglottis are obtained, and antibiotic therapy is initiated with a penicillinase-resistant antibiotic because of the high incidence of *H. influenzae* resistance to ampicillin.

Patients usually require endotracheal intubation for 24 to 72 hours while the swollen epiglottis returns to normal size. The patient may be allowed to breathe spontaneously through the endotracheal tube or may undergo mechanical ventilation.

2. A 5-year-old child with newly diagnosed leukemia is admitted to the pediatric intensive care unit in severe respiratory distress. Chest radiograph shows a widened mediastinum. Which one of the following measures is to be avoided during airway management in this child?

   A. Administration of muscle relaxants

   B. Endotracheal intubation

   C. Heliox administration

   D. Left lateral decubitus position

   Preferred response: A

Rationale

This child likely has an anterior mediastinal mass compressing the intrathoracic trachea. Because the symptoms produced by a malignant mass impinging on the trachea can worsen dramatically over several days, the child with respiratory compromise resulting from a mediastinal mass deserves rapid evaluation and aggressive medical therapy.

The child's refusal of certain body positions (mostly the supine position) to avoid dyspnea often precedes other signs and symptoms (cough, tachypnea, respiratory

distress) of an anterior mediastinal mass. Forcing the child to lie down may result in airway obstruction or even cardiac arrest. Conversely, airway obstruction by the mediastinal mass in the supine position is sometimes relieved by changing one's body position (lateral decubitus, prone, sitting).

Heliox (a mixture of 70% helium and 30% oxygen) administration may be beneficial in case there is severe narrowing of the trachea, because the characteristics of this mixture permit greater gas flow past areas of airway narrowing.

Endotracheal intubation is indicated only if respiratory function becomes severely compromised. This measure, of course, is only of benefit if the tip of the endotracheal tube can be advanced distal to the site of tracheal compression, which often means that main stem intubation is necessary to bypass the lesion if it is at the level of the distal trachea or carina. If intubation is necessary, sedation/anesthesia before laryngoscopy should be carried out while maintaining spontaneous ventilation, as positive pressure ventilation might be impossible. Thus muscle relaxants in this situation should be avoided.

Mechanical support with ECMO has been used to support patients with large mediastinal masses; however, the mass may distort the great vessels and pose unusual challenges for the ECMO team. Unfortunately, if the airway is lost or if the degree of cardiac compression is grave, ECMO might be the only option left to provide tissue oxygenation until the compression is relieved.

Chapter 51: Pediatric Acute Respiratory Distress Syndrome

---

1. You have just admitted to the PICU a 2-year-old child who was born at 25 weeks' gestation. He has chronic lung disease and is treated with oxygen 0.5 L/min per nasal cannula at home. He presented to the emergency department with a 2-day history of worse cough, congestion, and increased work of breathing. He was found to be in acute hypoxemic respiratory failure and was intubated due to severe hypoxemia and an increased work of breathing. His chest x-ray has chronic bilateral densities and a new right-sided density. He is being ventilated in pressure control pressure support with peak inspiratory pressure (PIP) = 28 cm H_2O, pressure support (PS) 16 cm H_2O, positive end-expiratory pressure (PEEP) = 8 cm H_2O, ventilator rate = 35 per minute, and fraction of inspired oxygen (FiO_2) = 0.8. His peripheral oxygen saturation (SpO_2) is 98%, and the mean airway pressure is 15 cm H_2O. Do you think he meets the criteria for pediatric acute respiratory distress syndrome (PARDS)?
   A. You think he meets the criteria based on his oxygenation saturation index = (80 × 15)/98 = 12.2.
   B. You think he meets the criteria but realize that he does not have ARDS because he has a new unilateral infiltrate.
   C. You think he meets the criteria but realize that he does not have ARDS because of his existing chronic lung disease.
   D. You think he meets the criteria but realize that you cannot determine his

oxygenation saturation index or his SpO_2/FiO_2 ratio because his SpO_2 is ≥97%.

Preferred response: D

Rationale

There is a strong linear association between SpO_2 and PaO_2 as long as the SpO_2 is ≤97%. The Pediatric Acute Lung Injury Consensus Conference (PALICC) definition of PARDS recommends use of the oxygenation index or oxygenation saturation index when a PaO_2 is not available. Although the PALICC definition of PARDS does not require new bilateral infiltrates, it recommends future studies investigate whether bilateral versus unilateral infiltrates improves discrimination of risk stratification.

2. On the third day of the hospitalization, the patient in question 1 develops progressively worse hypoxemia. His oxygen saturation index (OSI) is now 22. Data suggest that pulmonary-specific ancillary therapies that are indicated in children include which of the following?

   A. Exogenous surfactant

   B. High-frequency oscillatory ventilation (HFOV)

   C. Inhaled nitric oxide

   D. There are no data in children supporting specific pulmonary ancillary therapies.

   Preferred response: D

Rationale

There are no conclusive data supporting the specific pulmonary or pulmonary ancillary therapies in children. The most conclusive data supporting pulmonary therapy address limiting tidal volume in adults. Limiting the driving pressure and prone positioning seem to be beneficial in adults with ARDS, but there are no pediatric data. There are no studies supporting the use of exogenous surfactant, HFOV, or inhaled nitric oxide to improve mortality in children or adults.

3. Which of the following is a cause of direct lung injury?

   A. Near-drowning

   B. Sepsis

   C. Sickle cell disease

   D. Transfusions

   Preferred response: C

Rationale

Causes of direct lung injury include pneumonia, gastric content aspiration, lung contusion, hydrocarbon ingestion, smoke inhalation, and sickle cell disease. Near drowning, multiple emergent transfusions, and sepsis lead to acute lung injury as part of multiorgan failure.

Chapter 52: Ventilator-Induced Lung

Injury

1. What can prevent the development of ventilator-associated lung injury in mechanically ventilated patients?
   A. The application of low tidal volumes
   B. The application of large tidal volumes
   C. The application of a positive end-expiratory pressure (PEEP) level of 0 cm H_2O
   D. The application of frequent recruitment maneuvers
   Preferred response: A

Rationale

The main measure that has been shown to improve prognosis in mechanically ventilated patients with the acute respiratory distress syndrome (ARDS) is tidal volume reduction to 6 mL/kg as compared to 12 mL/kg of predicted body weight. Increasing evidence suggests that such ventilator settings may also be beneficial in mechanically ventilated patients who do not meet criteria for ARDS. A PEEP level of 0 cm H_2O is associated with the development of “low-volume” lung lesions and should be avoided. The other measures have not been shown to provide significant clinical benefit.

2. Which statement is true regarding the ventilator management of a patient with a severe acute respiratory distress syndrome?
   A. A tidal volume of 10 mL/kg of predicted body weight can be safely applied in most patients.
   B. A tidal volume of 6 mL/kg of predicted body weight can be safely applied in most patients.
   C. A tidal volume of 6 mL/kg of predicted body weight is safe for all patients.
   D. Prone positioning has not been shown to reduce mortality.
   Preferred response: B

Rationale

The main measure that has been shown to improve prognosis in mechanically ventilated patients with the acute respiratory distress syndrome (ARDS) is tidal volume reduction to 6 mL/kg as compared to 12 mL/kg of predicted body weight. Prone positioning has also been associated with a reduction in the mortality of ARDS patients having a PaO2/FiO2 ratio <150 mm Hg.

3. Which of the following is most likely to promote ventilator-induced lung injury (VILI)?
   A. Airway resistance
   B. End-inspiratory lung volume
   C. Level of positive end-expiratory pressure (PEEP)

D. Peak inspiratory pressure

Preferred response: B

Rationale

Webb and Tierney found that pulmonary edema rapidly developed in rats subjected to 45 cm H_2O peak airway pressure ventilation, whereas it did not develop in rats that underwent ventilation for a longer time with 14 cm H_2O peak airway pressure. Edema severity and rate of development increased with peak airway pressure magnitude. It was later confirmed that such a ventilation modality produces endothelial and epithelial cell damage and lung capillary permeability changes that result in nonhydrostatic pulmonary edema.

This edema formation is now generally believed to be the hallmark of VILI. The respective roles of increased airway pressure and increased lung volume in this injury were clarified when mechanical ventilations at high and low tidal volumes (V_T) were compared at identical (45 cm H_2O) peak airway pressures. The injury was found only in rats subjected to high V_T and not in those that underwent ventilation at high airway pressure in which lung distention was limited by thoracoabdominal strapping. Furthermore, pulmonary edema still developed in animals that underwent ventilation at high V_T by negative external distending pressure, confirming that excessive airway pressure is not the causal factor of this type of injury. This VILI, which depends mostly on end-inspiratory volume, has been called *volutrauma*. The alveolar pressure corresponding to end-inspiratory volume is the *plateau* airway pressure (measured at no-flow), and its clinical importance has been emphasized in a consensus conference on mechanical ventilation. Several investigators reached the same conclusions in other species using different protocols.

4. Which is the best ventilatory strategy for a 7-year-old patient with acute respiratory distress syndrome whose static pressure-volume curve is shown in Fig. Q52.4A?

   A. PEEP 5; V_T 200 mL

   B. PEEP 5; V_T 300 mL

   C. PEEP 8; V_T 180 mL

   D. PEEP 10; V_T 180 mL

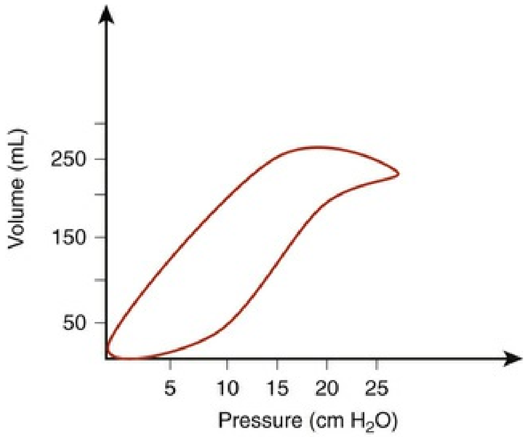


FIG. Q52.4A Static pressure-volume curve of the lung during inspiration and expiration.

Preferred response: D

Rationale

It has been recommended that the optimal PEEP should be set above the critical closing or critical opening pressure of the airways. This pressure can be deduced by the lower inflection point generated with static pressure-volume loops (see Fig. Q52.4B). As the lung is inflated from zero end-expiratory pressure, in many lungs an abrupt change in compliance occurs as denoted by the *lower inflection point.* It is generally thought that this is the critical opening pressure of the airways above which the alveoli and airways remain open. As the lung is further inflated in increments, the pressure-volume slope increases and then abruptly changes direction as noted in Fig. Q52.4B as the *upper inflection point.* It is generally thought that the upper inflection point reflects overdistention of the alveoli. The general recommendation is to keep the PEEP level above the lower inflection point and to keep the end-inspiratory pause pressure below the upper inflection point. Currently, bedside use of static pressure-volume loops to set PEEP is not a standard practice in infants and children. Therefore the level of PEEP should be set by titrating the level of PEEP and selecting the level by the maximal level of improvement in oxygenation compliance seen without affecting systemic hemodynamics. The repeated collapse and reopening of the lung units at low lung volume have been shown to contribute to VILI. A strategy combining recruitment maneuvers, low V_T, and higher PEEP has been shown to decrease the incidence of barotrauma or volutrauma.

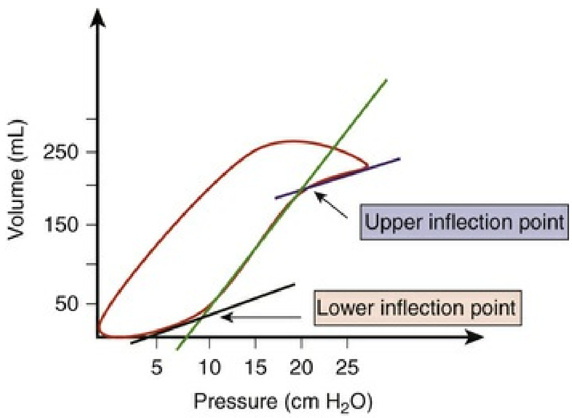

FIG. Q52.4B Static pressure-volume curves with upper and lower inflection points.

For the child in the vignette, the upper inflection point occurs with a V_T of 200 mL, so a lung protective strategy would maintain the V_T below 200 mL.

Chapter 53: Asthma

1. Which of the following is the predominant mechanism by which terbutaline causes bronchodilation?
   A. Activating the β-2 receptor, which increases cyclic adenosine monophosphate (cAMP) levels by augmenting its synthesis by adenylate cyclase
   B. Blocking the acetylcholine receptor, reducing the level of cyclic guanosine monophosphate (cGMP)
   C. Blocking the *N*-methyl-D-aspartate receptors in airway smooth muscle
   D. Inhibiting phosphodiesterase, which increases cAMP levels by preventing its degradation
   Preferred response: A

Rationale

An increase in cyclic adenosine monophosphate (cAMP) levels through adenylate cyclase–mediated synthesis is the predominant mechanism by which the β-agonists cause bronchodilation. Response B is the mechanism by which anticholinergic medications (eg, ipratropium bromide) work. Response C is one mechanism by which ketamine causes bronchodilatation. The methylxanthines (eg, aminophylline) also cause bronchodilatation by increasing cAMP. However, they work by inhibiting phosphodiesterase 4 and preventing the breakdown of cAMP (response D).

2. Which of the following statements regarding near-fatal asthma is true?
   A. A ventilation strategy of low respiratory rates (<12 breaths/min), moderate-to-high tidal volumes (8–12 mL/kg), and permissive hypercapnia has been proved to be associated with increased mortality and a rate of pneumothorax approaching 100%.
   B. Increasing positive end-expiratory pressure (PEEP) in mechanically ventilated asthma patients receiving neuromuscular blockade has been shown to have

unfavorable effects on lung volumes, airway pressure, and hemodynamics.

C. Ketamine is contraindicated during intubation due to its slow onset of action and tendency to cause bronchoconstriction.

D. Nearly all subjects have a history of severe persistent asthma with frequent ICU admissions in the 1 year preceding the episode of near-fatal asthma.

Preferred response: B

Rationale

Tuxen established in 1989 that increasing PEEP in patients with airway obstruction who are receiving neuromuscular blockade is associated with unfavorable increases in hyperinflation and intrathoracic pressures and frequent decreases in systemic blood pressure and venous oxygen saturation. In our practice, we set PEEP to zero in mechanically ventilated asthmatic patients during neuromuscular blockade (barring extenuating circumstances) and use minimal PEEP (less than auto-PEEP and not more than 8 cm H_2O) during spontaneous breathing. Mortality from near-fatal asthma is approximately 4% in the United States. In a study by the Collaborative Pediatric Critical Care Research Network, 11 fatalities were observed out of 261 children with near-fatal asthma (4.2%). Of these 11 children, 10 had suffered a cardiac arrest prior to PICU admission. In that same publication[1] the authors reported that 13% of subjects had no prior history of asthma (response D) and that only 29% of patients had an admission for asthma in the preceding year. Similarly, among 51 subjects who died from asthma in Australia, 32% of subjects had never been admitted to the hospital because of asthma prior to their death. Ketamine is commonly employed when intubating a child with near-fatal asthma (response C) due to its rapid onset, bronchodilatory effects, and beneficial hemodynamic outcomes. As described in the text, we suggest a ventilatory strategy that employs relatively low respiratory rates (6-12 breaths/min), tidal volumes of 8 to 12 mL/kg, and permissive hypercapnia (response A). When a similar strategy was used in 26 subjects, all patients survived and pneumothorax was uncommon.

3. Which of the following is true about the epidemiology of childhood asthma in the United States?

A. African Americans are more likely to require treatment in the emergency department but are much less likely to die from an acute asthma exacerbation compared with white persons.

B. Asthma prevalence has decreased sharply since the 1990s.

C. Emergency department visits and death rates have steadily declined since the early 2000s.

D. Once admitted to an intensive care unit, children with asthma are significantly more likely to require mechanical ventilation compared with adults.

Preferred response: C

Rationale

Although asthma prevalence has continued to increase, emergency department visits and death rates have declined. African Americans are more likely to require

treatment in the acute setting and exhibit a higher mortality than do white persons. Children with severe asthma exacerbations requiring critical care appear to require mechanical ventilation less frequently than do adults. Socioeconomic status is inversely and negatively correlated with asthma prevalence, morbidity, and mortality.

4. A 10-year-old boy is admitted to the pediatric intensive care unit with status asthmaticus refractory to initial treatment in the emergency department. The patient is agitated and exhibits severe intercostal and subcostal retractions with barely audible breath sounds. Mechanical ventilation is initiated because of hypoxemia and impending respiratory failure. Based on current best standards of care, which of the following ventilation strategies should be used after intubation?
   A. Permissive hypercapnia with the use of low respiratory rates and long expiratory times to avoid dynamic hyperinflation
   B. Pressure-controlled ventilation with a long inspiratory time and a short expiratory time
   C. The application of high levels of positive end-expiratory pressure (10 to 15 cm H_2O) to prevent derecruitment and atelectasis in the patient who has undergone neuromuscular blockade
   D. The use of high tidal volumes and rapid respiratory rates to deliver supraphysiologic minute ventilation and correct the respiratory acidosis
   Preferred response: A

Rationale

Mechanical ventilation of a child with asthma should follow a strategy based on long expiratory times, slow respiratory rates, and permissive hypercapnia to avoid dynamic hyperinflation. Attempts at normalizing arterial blood gases by delivering supraphysiologic minute ventilation increase the risk of air leak, hemodynamic instability, and death.

Chapter 54: Neonatal Respiratory Disease

1. Which of the following clinical conditions represents persistent pulmonary hypertension of the newborn due to maladaptation?
   A. Alveolar capillary dysplasia
   B. Bacterial pneumonia
   C. Congenital diaphragmatic hernia

D. Pulmonary hypoplasia secondary to renal agenesis
Preferred response: B

Rationale

Congential diaphragmatic hernia (CDH) is an example of pulmonary hypertension due to cardiopulmonary maldevelopment, as are fetal ductal closure, pulmonary hypoplasia, and alveolar capillary dysplasia. Bacterial pneumonia is an example of maladaptation.

2. A 36-week male infant born by spontaneous vaginal delivery is found to have biphasic stridor when he is agitated. His oxygen saturations are 100%, but he shows increased work of breathing when he becomes upset. He had mild hypotonia, and brain computed tomography demonstrated a mild subarachnoid hemorrhage. Based on these findings, what is the most likely cause of the infant's stridor?

A. Laryngomalacia

B. Tracheomalacia

C. Unilateral vocal cord paralysis

D. Vascular ring
Preferred response: A

Rationale

Biphasic stridor is usually the result of laryngeal obstruction. It tends to worsen with agitation, and it is the most common type of stridor in the neonatal period. Of the various causes of laryngeal obstruction, laryngomalacia is the most common laryngeal anomaly.

3. A 3-month-old term baby presents with a history of chronic wheezing that is unresponsive to bronchodilators and difficulty feeding. A chest x-ray reveals an abnormally shaped mediastinum. Which of the following is most likely?

A. Gastroesophageal reflux

B. Laryngomalacia

C. Tracheoesophageal fistula

D. Vascular ring
Preferred response: D

Rationale

Vascular compression of the trachea or main stem bronchus can result from improper regression of the embryonic branchial arch arteries during fetal development. The most common anomaly is a vascular "ring" consisting of a double aortic arch, in which the vessel completely encircles the trachea and esophagus. Other variants include an ectopic aortic arch (passing behind the esophagus) or an aberrant origin of the right brachiocephalic artery.

Vascular rings cause inspiratory stridor and expiratory wheezing, neither of which change appreciably with the infant's position. Intermittent worsening of symptoms

is sometimes seen when the infant is feeding, as boluses passing down the esophagus further compress the trachea. Feeding difficulty also may be present because of esophageal compression. When a previously undiagnosed child first presents with these symptoms, the child may be misdiagnosed as having tracheomalacia, bronchomalacia, or tracheobronchomalacia until further imaging confirms the cardiovascular abnormality. This condition also can be detected antenatally.

An abnormally shaped mediastinum on a chest film often provides a clue to this diagnosis. Endoscopy may identify tracheal or esophageal compression. An echocardiogram may define the nature of the vascular anomaly, but cardiac catheterization is sometimes necessary. Decisions regarding surgical correction of this defect depend on the relative compromise of the trachea and esophagus; however, the degree of compression may actually worsen as the infant grows.

4. A 37-week gestational age infant is born to a diabetic mother. The infant is vigorous at birth with a strong cry. His extremities are pink, and perfusion is excellent. At 4 hours of life, tachypnea and irritability develop, progressing to apnea. Oxygen saturation is 93% in room air. His lungs are clear on auscultation, and no murmur is present. What is the most probable cause for this child's symptoms?

   A. Apnea of prematurity

   B. Congenital heart disease

   C. Hyperviscosity syndrome

   D. Laryngomalacia

   Preferred response: C

Rationale

This child most likely has hyperviscosity syndrome. Hyperviscosity syndrome is a result of polycythemia and can occur in several situations, including twin-twin transfusion, maternal-fetal transfusion, delayed cord clamping, home delivery, maternal diabetes, small-for-gestational-age infants, postmature infants, and infants with Down syndrome or Beckwith-Wiedemann syndrome. Symptoms generally relate to the degree of hyperviscosity and can range from tachypnea to apnea, listlessness to irritability, and jitteriness to seizures. Hyperviscosity syndrome presents in the first few hours of an infant's life, and the presentation can mimic that in infants with congenital pneumonia, meconium aspiration, persistent pulmonary hypertension, or congenital heart disease.

This child is a full-term infant, thus discarding the possibility of apnea of prematurity. Because this child was born with a strong cry, it is unlikely that he has vocal cord paralysis. Unilateral vocal cord paralysis usually presents with a weak or sometimes hoarse cry. Bilateral vocal cord paralysis manifests with moderate to severe stridor, and some infants may have near total airway obstruction.

Infants with tracheomalacia may be mildly or severely affected, depending on the extent of involvement and the ability of surrounding supporting tissues to maintain airway patency. Affected infants generally have symptoms in the newborn period, but presentation may be delayed for many days or weeks if the defect is mild. In these milder cases, infants may remain symptom free until an intercurrent infection

leads to increased airway secretions and increased work of breathing. Symptoms include expiratory wheezing and respiratory distress including tachypnea and retractions, and the infant may receive a mistaken diagnosis of reactive airway disease; however, the use of bronchodilators may actually worsen the condition.

In the neonate, significant congenital heart disease typically presents in one of two ways: (1) cyanosis with minimal or no respiratory distress or (2) cardiorespiratory failure. Cyanotic lesions, such as transposition of the great vessels or tetralogy of Fallot, usually present in an infant who is blue but comfortable. Characteristically, congenital cyanotic heart disease is suspected in such an infant, even if a murmur is absent, particularly if the infant remains desaturated or hypoxemic in 100% oxygen. Less common in the neonate are the conditions that lead to early heart failure, such as an atrioventricular canal defect or a large ventricular septal defect. These infants generally are not cyanotic but are pale with marked respiratory distress and often a loud murmur; chest radiographs may show the classic signs of cardiomegaly and pulmonary vascular congestion.

Chapter 55: Pneumonitis and Interstitial Disease

---

1. Which of the following is the leading cause of lower respiratory tract infection in infants and children?

   A. Fungus

   B. *Staphylococcus aureus*

   C. *Streptococcus pneumoniae*

   D. Viral agents

   Preferred response: D

Rationale

Viral agents are the leading cause of lower respiratory tract infection in infants and children. Respiratory syncytial virus (RSV) followed by parainfluenza are the most commonly isolated viral agents. Streptococcus followed by *Staphylococcus aureus* are the leading causes of bacterial pneumonia but are far less common than viruses. Fungus and atypical pathogens are less common causes of lower respiratory infection in infants and children.

2. What are the signs and symptoms of gastroesophageal reflux disease that could lead to persistent aspiration and chronic pulmonary symptoms?

   A. Choking episodes, microcytic anemia, cough, bilateral diffuse infiltrates on chest x-ray

B. Esophagitis, macrocytic anemia, slight hyperinflation on chest x-ray

C. Macrocytic anemia, wheezing, atelectasis on chest x-ray

D. Spiking fevers, microcytic anemia, complete white-out on chest radiograph

Preferred response: A

Rationale

Choking episodes occur secondary to the retrograde passage of stomach contents into the esophagus and may occasionally cause stridor or even apnea. Microcytic anemia may occur secondary to repeated episodes of gastrointestinal blood loss from esophageal inflammation. Findings on chest x-ray are varied and may be only slight hyperinflation or may progress to bilateral diffuse infiltrates. Macrocytic anemia is more consistent with vitamin B_{12} or folic acid deficiency. Reflux does not generally cause spiking fevers or complete white-out on chest x-ray unless a massive aspiration event occurs such as during a trauma or with anesthesia.

3. What is the appropriate order of therapeutic objectives in the management of massive pulmonary hemorrhage?

A. Bronchoscopy (therapeutic or diagnostic), endotracheal intubation, fluid resuscitation

B. Endotracheal intubation, increase positive end-expiratory pressure (PEEP), fluid resuscitation, bronchoscopy (therapeutic or diagnostic)

C. Embolization of bleeding vessel, fluid resuscitation, endotracheal intubation

D. Fluid resuscitation, endotracheal intubation, embolization of bleeding vessel

Preferred response: B

Rationale

Securing a safe and stable airway is always the primary goal of any resuscitation. Increasing the end-expiratory pressure may provide a tamponade to the site of hemorrhage in an effort to prevent further profuse bleeding. After establishing an airway, the patient needs to be resuscitated to allow for increased stability for future short-term control of the bleeding. These measures could include bronchoscopy or embolization of the bleeding vessel.

4. Which of the following is present in the early stage of interstitial lung disease?

A. Decreased expiratory flow rates

B. Decreased resting arterial oxygen tension

C. Diminished carbon monoxide diffusing capacity

D. Increased carbon dioxide tension

Preferred response: C

Rationale

Changes in lung volumes in pulmonary parenchymal disease depend primarily on the intensity of the alveolitis and the stage of the disease process. Acute severe pneumonitis with an intense alveolitis is characterized by moderate to severe

reduction in both vital capacity and total lung capacity. It also is associated with a reduction in pulmonary compliance. In the early stages, patients with chronic interstitial diseases involving the lung parenchyma often have normal vital capacity and total lung capacity. There is subsequent reduction in lung volumes and pulmonary compliance as the disease progresses and pulmonary fibrosis ensues. Expiratory flow rates usually are preserved in pneumonitis involving the lung parenchyma, and major obstructive defects, although reported, are rare. The carbon monoxide diffusing capacity, one of the earliest and most sensitive tests of parenchymal inflammation, is diminished in persons with interstitial lung disease. A reduction in carbon monoxide diffusing capacity is not specific and may be found with other parenchymal disorders. In early parenchymal disease, resting arterial oxygen tension may be normal, but there is often mild alveolar hyperventilation with a reduction in alveolar carbon dioxide tension and widening of the alveolar-arterial oxygen gradients (PAO_2-PaO_2). With exercise, hypoxemia and an increased PAO_2-PaO_2 become exaggerated because of ventilation/perfusion imbalance. Ventilation/perfusion mismatch is attributed to regional alterations of flow, altered parenchymal compliance, and increased obstruction to pulmonary airflow. Progressive alveolitis and subsequent derangement of gas exchange lead to deterioration of ventilatory efficiency and markedly increased work of breathing. Adequate oxygenation may become impossible even with the use of high-flow supplemental oxygen. Resting hypercapnia, pulmonary hypertension, and eventual right ventricular dysfunction with heart failure are common sequelae.

5. A 15-month-old child is admitted to the pediatric intensive care unit with severe anemia (hemoglobin of 5 g/dL) due to pulmonary hemorrhage. The child's previous medical history is significant for six episodes of otitis media in the previous 12 months. The child was born full term with a birth weight of 3.2 kg. Currently the child weighs 6 kg. Besides pallor, tachycardia, and tachypnea, no other abnormalities are noticed on physical examination. Of the following, which is the most likely diagnosis for this child?

   A. Behçet syndrome

   B. Goodpasture syndrome

   C. Heiner syndrome

   D. Wegener granulomatosis

   Preferred response: C

Rationale

Pulmonary hemorrhage (PH) is defined as extravasation of blood into airways or lung parenchyma. Massive PH in adults is defined as blood loss of 600 mL or more in 24 hours. Loss of 10% of a patient's circulating blood volume into the lungs regardless of age causes a significant alteration in cardiorespiratory function and should be considered massive. The diagnosis of PH following an episode of silent bleeding is established by pulmonary hemosiderosis, which is the abnormal accumulation of iron within lung parenchyma and alveolar macrophages.

The classic clinical triad of hemoptysis, microcytic hypochromic anemia, and diffuse alveolar-filling opacities on chest radiograph is found in most episodes of diffuse/immune PH. Although the lung may be the only organ affected, more

frequently multiple organs are involved. In patients with PH, establishing which extrapulmonary organs are involved by the disease helps to narrow the differential diagnosis of which of the immune-mediated disorders is most likely present.

Diffuse parenchymal bleeding without evidence of extrapulmonary involvement occurs in idiopathic pulmonary hemosiderosis, Heiner syndrome, and drug-induced PH. Idiopathic pulmonary hemosiderosis, a disease of childhood, is a diagnosis of exclusion. Clinically, episodes of PH recur, with 30% to 50% of patients eventually dying of exsanguination or respiratory failure. Microscopic examination of the lungs is compatible with nonspecific injury rather than a specific cause such as vasculitis or immune deposits. Heiner syndrome, which affects children between the ages of 6 months and 2 years, usually manifests other symptoms, such as chronic rhinitis, recurrent otitis media, and growth retardation. Tests for precipitating antibodies to milk proteins are positive. Symptoms resolve when milk and milk products are eliminated from the diet.

In children with PH and either proteinuria, hematuria, or red cell casts, Goodpasture syndrome is the most likely etiology. The presence of a linear immunofluorescent staining of immunoglobulin and C3 along glomerular capillary walls and antibasement membrane antibody in the serum confirms the diagnosis of Goodpasture syndrome. Fifty percent of patients with Goodpasture syndrome die of asphyxia as a result of massive PH. The presence of sinusitis or bilateral, multiple cavitary pulmonary nodules and evidence of glomerulonephritis in patients with PH help distinguish Wegener granulomatosis from the other vasculitides.

The immune-mediated causes of PH with multisystem organ involvement often have characteristic physical findings to suggest the diagnosis. Serositis, arthritis, facial erythema, fever, and glomerulonephritis are present prior to the development of PH in patients with systemic lupus erythematosus (SLE). Ten percent of all cases of immune-mediated PH are associated with SLE. The onset of PH in persons with SLE is abrupt.

Recurrent uveitis, mucocutaneous ulcerations, and genital ulcerations in a patient with PH suggests Behçet syndrome as the etiology. Other clinical features seen with Behçet syndrome include arthritis, gastrointestinal disease, cardiovascular involvement, and central nervous system disease. A necrotizing vasculitis of small- to medium-sized arteries and veins and thromboses of the terminal vascular beds or vena cava confirm the diagnosis.

Chapter 56: Diseases of Pulmonary Circulation

---

1. Pulmonary vasodilators that do not cause systemic vasodilation and systemic hypotension are referred to as *selective pulmonary vasodilators.* Which of the following agents is a selective pulmonary vasodilator?

   A. Inhaled nitric oxide

   B. Intravenous milrinone

   C. Intravenous sildenafil

   D. Oral sildenafil

Preferred response: A

Rationale

Inhaled nitric oxide (iNO) is a specific pulmonary vasodilator and does not cause systemic hypotension. Although it has some effects on systemic circulation, it typically does not cause systemic hypotension in patients with pulmonary hypertension. It is inactivated by combining with hemoglobin to form methemoglobin with minimal effects on systemic vasculature.

2. In the management of pulmonary arterial hypertension in children, which statement is *most* appropriate regarding the use of phosphodiesterase 5 inhibitors?
   - A. All patients in the START-1 trial had exercise tolerance performed by bicycle ergometry as the primary end point at 16 weeks.
   - B. The FDA recommends the use of low-dose sildenafil in the chronic management of PH in children, as it improves exercise ability.
   - C. In the START-1 trial, the Kaplan-Meier estimates of 3-year survival rates from the start of sildenafil were 94%, 93%, and 88%, respectively, for patients randomized to low-, medium-, and high-dose sildenafil.
   - D. Tadalafil has a lower affinity for PDE-5 compared with the other PDE inhibitors.

   Preferred response: C

Rationale

The START-1 (sildenafil in treatment-naïve children aged 1 to 17 years with pulmonary arterial hypertension) pediatric trial was a landmark study, with the primary end point of exercise tolerance using bicycle ergometry testing only in those subjects able to perform (about half of study patients). The controversy arose when the mortality was assessed on the yearly basis in the low-dose (10 mg), medium-dose (10–40 mg), and high-dose (20–80 mg) groups. By 3 years, the hazard ratios for mortality were 3.95 (CI: 1.46-10.65) for high- versus low-dose and 1.92 (CI: 0.65-5.65) for medium- versus low-dose sildenafil. Kaplan-Meier estimates of 3-year survival rates from the start of sildenafil were 94%, 93%, and 88%, respectively, for patients randomized to low-, medium-, and high-dose sildenafil in the START-1 trial. In August 2012, the FDA issued a strong warning against the chronic use of sildenafil for pediatric patients (1-17 years of age). The warning states that (1) children taking a high dose of Revatio had a higher risk of death than children taking a low dose and (2) low doses of Revatio are not effective in improving exercise ability. However, future statements clarified that the earlier FDA statement was not intended to suggest that Revatio should never be used in children and can be used in acute critical care settings and in infants with bronchopulmonary dysplasia and pulmonary hypertension. One of the advantages of tadalafil is its strong affinity for PDE-5 compared to other PDE inhibitors and hence its longer duration of action.

3. What is the *least* accurate statement regarding the management of pulmonary arterial hypertension (PAH) in children?
   - A. Coadministration of sildenafil with ketoconazole or rifampin should be

avoided.

B. Due to the risk of hepatic toxicity, the FDA requires that liver function tests be performed at least once in 3 months in patients on endothelial receptor antagonists such as bosentan.

C. Nitric oxide is currently the first-line drug in the acute management of PAH or in cases of postoperative PAH arising from congenital heart disease (CHD) repair.

D. There is a mutual pharmacokinetic interaction between bosentan and sildenafil that may influence the dosage of each drug in a combination treatment.

Preferred response: B

Rationale

As sildenafil is metabolized by hepatic CYP450, coadministration of sildenafil with CYP3A inducers or inhibitors such as ketoconazole or rifampin should be avoided. There is a mutual pharmacokinetic interaction between bosentan and sildenafil that may influence the dosage of each drug in a combination treatment. Bosentan decreases the maximum plasma concentration of sildenafil (Cmax) by 55.4% on day 16, whereas sildenafil increased bosentan Cmax by 42%, hence close monitoring is advisable with coadministration. Nitric oxide (NO) is currently the first-line drug in the acute management of PAH or in cases of postoperative PAH arising from CHD repair or other causes. Due to the risk of hepatic toxicity, the FDA requires that liver function tests be performed at least monthly and hematocrit every 3 months on patients on endothelial receptor antagonists such as bosentan. There is concern that the endothelin antagonists as a class may be capable of causing testicular atrophy and male infertility.

4. Which of the following statements most accurately reflects acute vasoreactivity testing in persons with pulmonary arterial hypertension (PAH)?

A. Acute response to vasodilator testing is defined as a decrease in mean pulmonary arterial pressure by at least 10 mm Hg to an absolute level of less than 40 mm Hg with a decrease in cardiac output.

B. Acute vasodilator testing is indicated in patients with significantly elevated left ventricular filling pressures.

C. Inhaled nitric oxide (iNO) is the most commonly used drug for acute vasoreactivity.

D. Responders to acute vasodilator testing (AVT) are more likely to respond to any therapy specific to PAH than are nonresponders.

Preferred response: C

Rationale

Vasoreactivity testing is an essential component in the diagnostic evaluation of PAH because it has therapeutic implications. Responders are more likely to respond to oral CCBs than are nonresponders and seem to have a better prognosis. AVT is usually performed during the same procedure as the diagnostic right heart catheterization. AVT is performed using iNO, intravenous PGI_2, or intravenous

adenosine. The most commonly used drug for AVT is iNO at doses of 20 to 40 ppm for 5 minutes. Hemodynamic measurements are recorded prior to and after administration of iNO, and the drug is discontinued completely. Based largely on data from Sitbon and colleagues, the European Society of Cardiology and American College of Chest Physicians guidelines propose that the acute response to vasodilator testing be defined as a decrease in mean pulmonary arterial pressure by at least 10 mm Hg to an absolute level of less than 40 mm Hg without a decrease in cardiac output. Patients with PAH due to conditions other than idiopathic PAH, such as BMPR2 genotype or anorexigen-induced PAH, have a very low rate of long-term responsiveness to oral CCB therapy. Accordingly, the decision to proceed with AVT in such patients should be individualized. AVT testing is not indicated, and may be harmful, in patients with significantly elevated left heart filling pressures.

5. Which of the following statements is true regarding vasoactive mediators and their effect on vascular smooth muscle cells?
   - A. Nitric oxide stimulates the formation of cyclic adenosine monophosphate (cAMP).
   - B. Phosphodiesterase 3 (PDE-3) inhibitors such as milrinone increase cAMP levels.
   - C. Phosphodiesterase 5 (PDE-5) inhibitors such as sildenafil increase cAMP levels.
   - D. Prostacyclin increases the formation of cyclic guanosine monophosphate (cGMP).

   Preferred response: B

Rationale

Vasodilators such as NO and prostacyclin relax vascular smooth muscle by increasing intracellular concentrations of the second messengers cGMP and cAMP, respectively. Inhibition of the cGMP degrading phosphodiesterase (PDE-5) by sildenafil and inhibition of the cAMP degrading phosphodiesterase (PDE-3) by milrinone offer additional tools to achieve pulmonary vasodilation in patients with persistent pulmonary hypertension. Type 5 phosphodiesterase (PDE-5) is primarily responsible for degradation of cGMP to the inactive metabolite GMP. One way of augmenting the concentration of cGMP in pulmonary vessels is by inhibiting the activity of PDE-5. PDE-5 inhibitors, such as sildenafil and tadalafil, might therefore be expected to prolong the vasodilating effects of cGMP. Sildenafil is a potent and selective inhibitor of cGMP-specific PDE-5.

6. Which of the following statements is true regarding fetal circulation and transition at birth?
   - A. All the blood draining into the right atrium from the inferior vena cava (IVC) enters the left atrium.
   - B. Pulmonary vascular resistance falls and systemic vascular resistance increases soon after birth.
   - C. The ductus arteriosus shunts blood from right to left (pulmonary artery to aorta) soon after birth.
   - D. The highest PaO_2 levels in the fetus are in the umbilical arteries.

   Preferred response: B

Rationale

Oxygenated blood (PaO_2 approximately 30-40 mm Hg) returning from the placenta in the umbilical vein splits in the liver, with slightly more than half passing through the ductus venosus to the IVC. The oxygenated blood streams along the medial aspect of the IVC as it enters the right atrium. Approximately two-thirds of the IVC flow is directed toward the foramen ovale by the eustachian valve and the septum primum and enters the left atrium. The remaining third of IVC flow mixes with the blood from the superior vena cava and enters the right ventricle. The majority of the right ventricular output enters the ductus arteriosus and the descending aorta. A small portion enters the lungs via the pulmonary arteries. The ratio of blood flow to the pulmonary arteries to the flow that traverses the ductus arteriosus is determined by the fetal pulmonary vascular resistance (PVR).

The first stage of transitional circulation is essentially a fetal pulmonary circulation that is characterized by high pressure and low flow because of both passive and active elevation of PVR. Thus PVR exceeds systemic vascular resistance, resulting in right atrial and ventricular pressures exceeding left atrial and ventricular pressures. High PVR results in right-to-left shunting of blood across the foramen ovale, and most of the blood ejected by the right ventricle flows across the ductus arteriosus into the descending aorta. The second stage of normal transition is accomplished when the fluid-filled fetal lungs are distended with air during the first breath. A rapid decrease in PVR occurs with mechanical distention of the pulmonary vascular bed. The entry of air into the alveoli improves oxygenation of the pulmonary vascular bed, further decreasing PVR. At birth, PVR decreases dramatically. As PVR becomes less than systemic, flow across the ductus reverses. Within the first 5 minutes after birth, oxygen-induced vasodilation and lung expansion decrease PVR to approximately half of systemic resistance. During the first few hours after birth, the ductus arteriosus closes, largely in response to the increase in oxygen tension. At this point the normal postnatal circulatory pattern is established.

Chapter 57: Mechanical Ventilation and Respiratory Care

---

1. Which of the following correctly describes the pressure-regulated volume control mode of ventilation?
   A. Patient-triggered, flow-controlled, flow-cycled ventilation
   B. Patient-triggered, flow-controlled, time-cycled ventilation
   C. Patient/machine-triggered, pressure-controlled, time-cycled ventilation
   D. Patient/machine-triggered, pressure-controlled, flow-cycled ventilation
   Preferred response: C

Rationale

The pressure-regulated volume control mode of ventilation (PRVC) is a dual-control mandatory mode. Each breath is either patient triggered (SIMV or assist control) or machine triggered. The primary control is pressure. Between breaths, volume is controlled primarily by adjusting the pressure control level. Cycling is by time. All the other modes are common misconceptions of this mode.

2. Which of the following is associated with a high risk (>25%) of extubation failure?
   A. Dynamic compliance of 0.9 mL/kg/cm H_2O
   B. Fraction of inspired oxygen (FiO_2) of 0.45 to maintain SpO_2 of 95%
   C. Fraction of minute ventilation provided by the ventilator of 20%
   D. Spontaneous tidal volume without pressure support of 6 mL/kg
   Preferred response: B

Rationale

Responses A, C, and D are associated with <10% risk of failure. Only response B is associated with at least a 25% rate of failure.

Self-Assessment Questions

3. Which of the following is used to define inadequate oxygenation?
   A. Alveolar-to-arterial gradient of 150 torr with a fraction of inspired oxygen of 1
   B. Calculated intrapulmonary shunt of 10%

C. Arterial hemoglobin saturation of 91% in room air

D. PaO_2/fraction of inspired oxygen (FiO_2) of 250

Preferred response: D

Rationale

Inadequate oxygenation, objectively, is defined as PaO_2 less than 60 torr or an arterial hemoglobin oxygen saturation of <90% in room air. Oxygenation also can be expressed as the ratio of PaO_2 to FiO_2. Inadequate oxygenation also can be defined as a PaO_2/FiO_2 ratio of less than 300. Other indices include an alveolar-to-arterial oxygen gradient of more than 300 torr with an FiO_2 of 1 and a calculated or measured intrapulmonary shunt fraction greater than 15%. Inadequate oxygenation due to intrapulmonary shunting can be overcome with the addition of an increased inspired oxygen concentration, provided the magnitude of the shunt is less than 15% (Fig. Q57.3). Intrapulmonary shunt can be decreased with the reexpansion of collapsed alveoli or with the decrease of the fraction of pulmonary blood flow going to the collapsed alveolar segments.

4. You are using mechanical ventilation to treat a child with acute respiratory distress syndrome. You chose to deliver pressure-regulated mandatory breaths. The child is receiving neuromuscular blocking agents. Which are the appropriate phase variables in this situation?

A. Flow triggered, flow limited, pressure cycled

B. Pressure triggered, flow limited, pressure cycled

C. Time triggered, pressure limited, volume cycled

D. Time triggered, pressure limited, time cycled

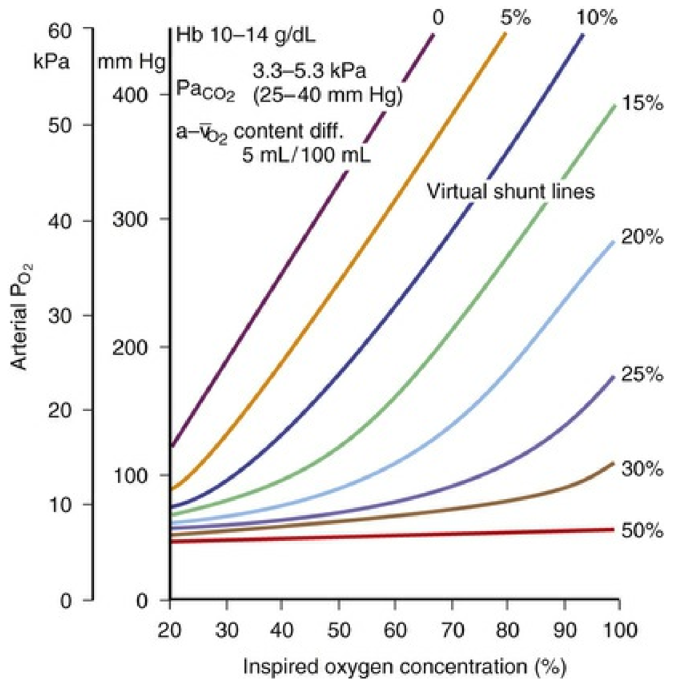

FIG. Q57.3

Preferred response: D

Rationale

The inspiratory phase starts when a variable measured in the circuit or at the airway reaches a preset value. This variable can be pressure, volume, flow, or time and is called the trigger variable. Pressure or flow triggering requires a patient's effort. On the other hand, time-triggered breaths do not require a patient's effort but can be synchronized to the patient's efforts. Pressure-regulated ventilation can be either pressure-cycled or pressure-limited, time-cycled ventilation. In pressure-cycled ventilators, inspiration is terminated when a preset pressure limit is reached. In this mode of ventilation, the inspiratory time may vary depending on the changes in resistance and compliance of the total respiratory system. This mode of ventilation is not widely used today except for intermittent positive pressure breathing treatments. Pressure-limited, time-cycled ventilation is most commonly used in the neonate with respiratory distress syndrome and in children with acute respiratory distress syndrome. In this mode, inspiratory and expiratory times are constant, and the peak inspiratory pressure reaches a preset limit early in inspiration and is then maintained at that level during the remainder of the inspiratory phase. Usually a high flow rate is used (4 to 10 L/kg/min). The tidal volume delivered depends on the compliance and resistance of the ventilator circuit and the patient's lungs. Pressure-controlled ventilation results in higher mean airway pressure for the same amount of minute ventilation (Fig. Q57.4). The figure shows the time course of changes in airway pressure, inspiratory flow, and lung volume with normal lungs, lungs with decreased compliance, and lungs with increased resistance. As shown in the figure, with peak inspiratory pressure remaining the same, the lung volume delivered is affected by changes in lung compliance and airways resistance.

Because this child is receiving neuromuscular blocking agents, the breaths cannot be flow triggered or pressure triggered, and thus responses A and C are incorrect. Response B is incorrect because the mode of ventilation is pressure regulated and can be either pressure cycled or pressure limited, time cycled.

5. Which of the following phase variables during a ventilator-assisted breath is responsible for terminating inspiration?

   A. Flow-limited breath

   B. Pressure-cycled breath

   C. Pressure-limited breath

   D. Time-triggered breath

   Preferred response: B

Rationale

All ventilators are equipped with mechanisms to provide four basic functions: (1) inflate the lungs, (2) terminate lung inflation, (3) allow lungs to empty, and (4) start lung inflation. The ventilator performs these functions through four phases: (1) the inspiratory phase, (2) the changeover from the inspiratory to the expiratory phase, (3) the expiratory phase, and (4) the changeover from the expiratory phase to the inspiratory phase. The inspiratory phase starts when a variable measured in the

circuit or at the airway reaches a preset value. This variable can be pressure, volume, flow, or time and is called the trigger variable. Pressure triggering or flow triggering requires a patient's effort. On the other hand, time-triggered breaths do not require a patient's effort but can be synchronized to the patient's efforts. During inspiration, a tidal breath is delivered to the lung. The volume of the tidal breath delivered to the patient depends on several factors: (1) the total pressure (P_{tp}) generated, (2) the compliance and resistance of the ventilator circuit, (3) the impedance to inflation of the patient's lungs, (4) leaks in the circuit, (5) leaks around the endotracheal tube, and (6) the limitation or regulation of inspiratory phase variables (pressure, flow, or volume). Limitation or regulation of the inspiratory pressure, volume, or flow does not terminate inspiration. Modern ventilators such as the Siemens Servo 300 can control more than one phase variable during inspiration. Termination of inspiration depends on the cycling mechanism. Cycling refers to the mechanism by which inspiration is terminated and expiration is initiated. All ventilators require a trigger mechanism to cycle. The trigger for cycling may be a predetermined time (time cycling), a predetermined pressure (pressure cycling), a predetermined volume (volume cycling), or a predetermined flow (flow cycling). Most conventional ventilators used in infants and children today are time-cycled or volume-cycled ventilators.

6. Based on the following figure (Fig. Q57.6), which statement about patients B and C is correct? (Patient A has normal lungs.)
   A. Both patients B and C have lungs with increased resistance.
   B. Both patients B and C have lungs with decreased compliance.
   C. Patient B's lungs have increased resistance, and patient C's lungs have decreased compliance.
   D. Patient B's lungs have decreased compliance, and patient C's lungs have increased resistance.

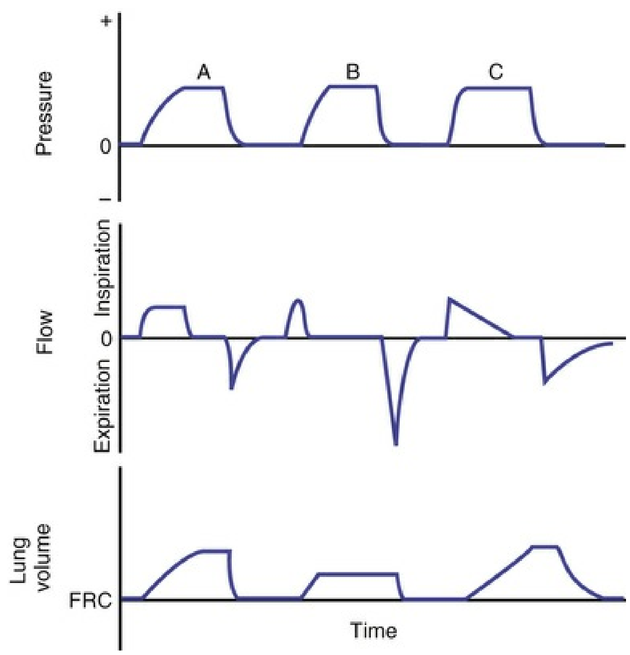

FIG. Q57.6

Preferred response: D

Rationale

With increased compliance, the tidal volume delivered is decreased (patient B). With increased resistance, it takes longer to deliver the tidal volume (patient C).

7. Which best describes the phase variables for pressure-support ventilation?
   A. Patient triggered, flow limited, pressure cycled
   B. Patient triggered, pressure limited, flow cycled
   C. Pressure triggered, flow limited, patient cycled
   D. Pressure triggered, patient limited, flow cycled

   Preferred response: B

Rationale

Pressure-support ventilation (PSV) is a form of assisted ventilation in which the ventilator assists the patient's own spontaneous effort with a mechanical breath with a preset pressure limit. As with any form of support that is designed to respond to the patient's effort, the inspiratory pressure assist of PSV requires a signal to trigger the demand valve to initiate flow. The patient's spontaneous breath creates a negative pressure (pressure triggering) or a change in flow through the circuit (flow triggering), which triggers the ventilator to deliver a breath. With initiation, the machine delivers high inspiratory flow to achieve a peak airway pressure level that is selected by the operator. The pressure limit stays constant as long as the patient's inspiratory effort is maintained with a variable gas flow rate from the ventilator. As inspiration continues, the inspiratory flow rate decreases. A threshold reduction in the flow rate is a signal to terminate the inspiratory assist, with the opening of an expiratory valve, after which passive exhalation occurs. The termination signal can be a predetermined percentage of the peak inspiratory flow (10% or 25%) or a fixed flow (usually 5 L/min). Many ventilators also incorporate backup flow termination criteria, such as the duration of inspiration greater than 5 seconds or an increase in the airway pressure above the set pressure support level (eg, when a patient attempts to cough). In summary, PSV is patient triggered, pressure limited, and flow cycled. PSV is entirely dependent on the patient's effort; if the patient becomes apneic, the ventilator will not provide any mechanical breath.

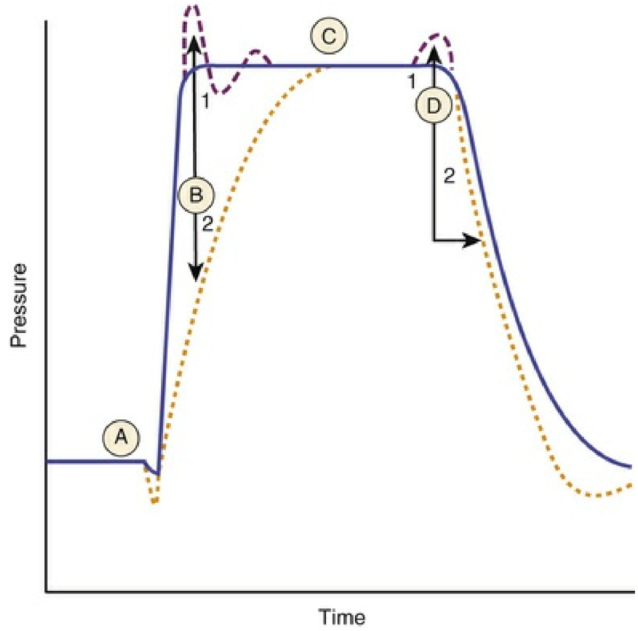

FIG. Q57.7 Components of a pressure-support breath. *Point A* is the patient's effort indicated by a negative deflection. When the ventilator senses this trigger (change in pressure or flow), it will deliver flow to reach the desired pressure-support level *(Point B)* as rapidly as possible. Ventilator-delivered flow is then servo-adjusted to patient demand to maintain this pressure plateau *(Point C)*. Inspiration is terminated when a minimal flow criterion is reached *(Point D)* and airway pressure returns to baseline. (Reproduced from MacIntyre NR. Pressure support ventilation. Mechanical ventilation and assisted respiration. In Grenvik A, Downs J, Rasanen J, Smith R, eds. Contemporary Management in Critical Care. New York: Churchill Livingstone; 1991.)

Chapter 58: Noninvasive Ventilation

1. Which of the following is a contraindication to noninvasive ventilation (NIV)?
   A. Bulbar palsy
   B. Congestive cardiac failure
   C. Extubation after prolonged mechanical ventilation
   D. Respiratory failure from lung metastases
   Preferred response: A

Rationale

The abilities to protect the airway and to handle secretions are criteria for considering a candidate for NIV. With bulbar palsy, the likelihood of aspirating oral secretions into the lung increases and therefore is a contraindication for NIV.

2. Which of the following is a sign of success with short-term noninvasive ventilation?
   A. Abdominal paradox
   B. Decreased blood pressure

C. Increased heart rate

D. Decreased retractions

Preferred response: D

Rationale

An increased heart rate and decreased blood pressure may reflect a negative heart-lung interaction due to the positive airway pressure during NIV and should be avoided. Abdominal paradox should be reduced with NIV, not increased. Decreased retractions signify decreased work of breathing associated with NIV.

3. Which of the following patients would most likely benefit from noninvasive ventilation (NIV)?

   A. A 3-month-old girl with respiratory syncytial virus respiratory infections and abundant secretions

   B. A 7-year-old girl whose status is postanterior cricoid split

   C. A 10-year-old girl with rapidly progressive ascending weakness after an influenza vaccination

   D. A 14-year-old boy with respiratory distress and pneumonia with a PaO_2/fraction of inspired oxygen (FiO_2) of 250

   Preferred response: D

Rationale

Three adult studies have demonstrated that the use of NIV reduced the duration of mechanical ventilation, reduced the incidence of nosocomial pneumonia, and reduced the duration of the patient's hospital stay. Similar pediatric studies are lacking. NIV to facilitate extubation should be carried out only if the following criteria are met: (1) the patient is awake and alert, (2) the patient has intact bulbar function with a preserved cough reflex, (3) the patient has minimal airway secretions, (4) the patient is able to breathe spontaneously, (5) the patient has stable hemodynamic status, (6) the patient does not have gastric distention, and (7) the patient has a requirement for supplemental oxygen ≤40%. Some adult studies have examined the use of NIV for postextubation respiratory failure—that is, respiratory failure that develops after extubation on complete spontaneous breathing. The rationale for the use of NIV in this circumstance is the avoidance of endotracheal intubation. In at least one study in adults, this approach was shown to increase the time from respiratory failure to intubation with an increase in mortality rate. It is difficult to extrapolate from adult studies to pediatrics. It is possible that some children may benefit from the institution of NIV for postextubation respiratory failure.

TABLE Q58.3

Selection Guidelines for Short-Term Noninvasive Ventilation

A. Potentially Reversible Condition
B. Need for *Moderate* Ventilatory Assistance
Moderate to severe increase in work of breathing

Tachypnea
Retractions
Paradoxical breathing
Accessory muscle use
Gas exchange criteria
Ventilatory failure ($PaCO_2$ >45 mm Hg with a pH <7.35)
Oxygenation failure (PaO_2/FiO_2 ratio <300)
C. No Contraindications to NIV
Respiratory or cardiac arrest
Unstable (hypotension, shock)
Poor airway protective reflexes
Recent upper airway and esophageal surgery
Excessive secretions
Uncooperative
Agitation
Untreated pneumothorax
Inability for a good mask fit
Rapidly progressive neuromuscular weakness (eg, Guillain-Barré syndrome)

Chapter 59: Extracorporeal Life Support

1. A 6-month-old boy has been on venoarterial extracorporeal membrane oxygenation (ECMO) through the cervical vessels for 2 days to treat respiratory failure associated with respiratory syncytial virus (RSV) pneumonia. He was doing well until the venous return alarm on the ECMO circuit began to ring and circuit flow was interrupted. He is now crying, and the venous line does not appear to be kinked. His blood pressure, heart rate, and perfusion are normal. What is the *most* likely cause of the alarm?

   A. Increased intrathoracic or intraabdominal pressure with crying

   B. Hypervolemia after receiving blood

   C. Hypovolemia related to capillary leak syndrome

   D. Pericardial tamponade

   Preferred response: A

Rationale

Increased intrathoracic or intraabdominal pressure will restrict venous return to the right atrium and thus decrease venous return to the ECMO circuit.

2. A patient on venovenous (VV) extracorporeal membrane oxygenation (ECMO) support has a mixed venous oxygen saturation reading on the ECMO circuit of 65% but is hypoxic with an arterial saturation of 72%. Increasing the ECMO flow brings the venous saturation to 73%, but the patient's arterial saturation does not improve. What is the *most* likely cause of this response?

   A. Hypovolemia

   B. Loss of oxygen to the patient's ventilator circuit

   C. Recirculation of the VV circuit

   D. Severe anemia

   Preferred response: C

Rationale

Increasing flow to the venovenous circuit can increase recirculation. This means that oxygenated blood returning from the ECMO pump is drawn immediately back into the venous drainage cannula. This will increase the saturation of oxygenated blood within the ECMO circuit and give a falsely high venous saturation reading in the circuit as compared to what the patient' s system is actually seeing. The recirculated blood will not be delivered to the patient's systemic circulation, and thus oxygen delivery and saturation will not improve. Recirculation can sometimes be reduced by *decreasing* the ECMO flow and allowing more oxygenated blood to be delivered systemically. Other measures to improve oxygenation include increasing oxygen content by hemoglobin transfusion; reducing oxygen extraction by correcting fever, pain, and the like; or increasing cardiac output from the patient by inserting another venous drainage cannula or converting to venoarterial support.

3. An 8-month-old girl born at 32-weeks' gestation is placed on venovenous (VV) extracorporeal membrane oxygenation (ECMO) because of worsening pneumonia. Her oxygen index on a high-frequency oscillator ventilator is greater than 60. An echocardiogram done prior to the initiation of ECMO showed normal cardiac function. Which of the following best describes VV ECMO?

   A. Myocardial stunning is a common feature.

   B. Native cardiac function is relied on for maintaining systemic circulation.

   C. Patients are at increased risk for cerebral and systemic emboli.

   D. Percutaneous cannulation of the internal carotid artery is common.

   Preferred response: B

Rationale

VV ECMO differs from venoarterial ECMO in that blood is both withdrawn and reinfused into the patient's venous circulation. Cannulation can be introduced via either the cervical or the femoral vessels. Several types of multiple lumens, single cannulas exist. One, manufactured by Origen Inc. (Austin, Texas), is available in sizes from 12 to 18 French and can support a patient weighing up to 12 kg. This cannula is placed into the right internal jugular vein and requires only one surgical site. The drainage and infusion lumens in this cannula are separated by a distance of a few centimeters. Careful placement and orientation of the cannula can reduce recirculation of reinfused blood from the ECMO circuit, although some amount of recirculation always occurs. A new VV cannula manufactured by Avalon Laboratories Inc. (Rancho Dominguez, California) also has become available in sizes from 13 French to 31 French and is able to obtain flow rates to support even large adult patients. This cannula has two drainage lumens, one that is positioned in the inferior vena cava and one positioned in the superior vena cava. ECMO also can be provided via two (or more) separate access sites. The right internal jugular vein and the femoral vein provide access in the majority of patients. Patients with VV cannulation may have venous blood drained from the right atrium via the internal jugular vein or from the inferior vena cava via the femoral vein.

Because blood is both withdrawn and reinfused into the venous circulation, adequate native cardiac function must exist to provide the "pumping" of oxygenated

ECMO return to the patient's systemic circulation. One factor that may influence cardiac function during VV ECMO is that well-oxygenated blood returning from the ECMO circuit will enter the right heart. This highly oxygenated blood may reduce pulmonary artery pressure by reducing pulmonary vascular resistance, which may in turn improve right heart function. Likewise, highly saturated blood ejected from the left ventricle to the coronary arteries may improve myocardial blood flow and cardiac performance. For these reasons, some clinicians will initiate VV ECMO even in patients with cardiac dysfunction and transition to venoarterial ECMO if support is inadequate. Other clinicians prefer to use venoarterial ECMO preferentially if cardiac dysfunction exists.

Another feature of VV ECMO is that because blood is withdrawn and reinfused into the venous side of the circulation, some of the return coming from the ECMO circuit will be drained by the venous drainage cannula before it goes through the patient's heart into the systemic circulation. This phenomenon is known as *recirculation,* and it can be a major limiting factor in providing adequate patient support with VV ECMO. With double lumen cannulas placed via the right internal jugular vein to the right atrium, careful orientation of the inflow lumen toward the tricuspid valve may limit recirculation. The larger separation of drainage and inflow lumens with the Avalon device seems to be associated with fewer recirculation difficulties.

With two-site venous cannulation, recirculation can be limited to some degree by ensuring that some distance separates the end tips of the drainage and infusion cannulas in the body. Recirculation also can be reduced by draining from the femoral vein cannula and reinfusing into the right internal jugular vein cannula. The extent of recirculation can be estimated by following the venous saturation in the extracorporeal life support circuit; high levels of recirculation will elevate the displayed venous saturation on the drainage line because some of the highly saturated return from the extracorporeal life support circuit is immediately drawn out by the drainage cannula. Whether VV cannulation will adequately capture the patient's cardiac output for ECMO support depends on how large the cannulas are, where they lie in the vessel, and how much overall ECMO support the patient requires.

4. Which of the following factors is associated with an increased chance of survival in children placed on ECMO during arrest?

   A. Metabolic abnormality

   B. Renal insufficiency

   C. Underlying cardiac illness

   D. Use of sodium bicarbonate or tromethamine during arrest

   Preferred response: C

Rationale

A review from the National Registry of Cardiopulmonary Resuscitation found that 199 pediatric patients placed on ECMO during arrest had an overall survival rate of 44%. In 59 survivors in whom a neurologic outcome was recorded, 95% had favorable outcomes based on Pediatric Cerebral Performance scores. By multivariate analysis, renal insufficiency, metabolic or electrolyte abnormality at the time of

arrest, and use of sodium bicarbonate or tromethamine were associated with decreased survival. Underlying cardiac illness was associated with an increased survival to discharge.

Chapter 60: Development, Structure, and Function of the Brain and Neuromuscular Systems

A previously healthy 3-year-old boy presents with a fever of 41°C, nuchal rigidity, and photophobia. A lumbar puncture reveals cerebrospinal fluid (CSF) with a markedly elevated WBC count. The child is treated with ceftriaxone, vancomycin, and acyclovir and admitted to the PICU for observation. CSF culture grows *Streptococcus pneumoniae* that is sensitive to ceftriaxone. The fever resolves over the next 72 hours with improvement in his clinical exam. On the fourth day of admission, he complains of headache in the morning and vomits. In the afternoon, he acutely becomes unresponsive with a dilated and fixed right pupil. An emergent head CT shows a nonobstructive hydrocephalus with enlargement of the lateral ventricles and effacement of the cerebral sulci.

1. Of the following, which option best explains the pathophysiology of his hydrocephalus?
   A. Decreased CSF absorption due to blockage of the aqueduct of Sylvius with bacterial and cellular debris
   B. Decreased CSF absorption due to blockage of arachnoid granulations with bacterial and cellular debris
   C. Increase in CSF production due to inflammation
   D. Low-pressure hydrocephalus due to loss of cerebral cortical volume
   Preferred response: B

Rationale

Bacterial debris and cellular breakdown products in CSF can lead to blockage and thickening of arachnoid granulations and in some cases hydrocephalus and intracranial hypertension.

2. During the CT scan, the boy develops hypertension (blood pressure, 200/120 mm Hg) and bradycardia to 30 beats/min, loses pupillary reflex in his left eye, and develops gasping intermittent respirations. His symptoms are most consistent with compression of which brain structure?
   A. Cerebellum
   B. Cortex
   C. Optic nerves
   D. Pons
   Preferred response: D

Rationale

Compression on the pons, in this case as a consequence of intracranial hypertension leading to herniation, produces the classic Cushing triad of hypertension, bradycardia, and irregular breathing.

3. The patient is treated with hyperosmolar agents to reverse his herniation and is endotracheally intubated. A member of the neurosurgery staff places an external ventricular drain at the patient's bedside, which resolves his intracranial hypertension (ICP <20 mm Hg). An electroencephalogram reveals status epilepticus. Midazolam boluses and a rapidly escalating midazolam infusion fail to control his seizures. The patient is then converted from midazolam to a pentobarbital infusion, which controls his seizures. He is weaned off pentobarbital in 3 days, extubated on hospital day 11, and leaves the PICU on day 12. A neurodevelopmental screen 6 months later demonstrates mild residual hearing loss and mild attention deficits. What is the most likely reason pentobarbital but not midazolam controlled his seizures?
   - A. Pentobarbital acts on glycine receptors, whereas midazolam acts on GABA receptors.
   - B. Pentobarbital penetrates the blood-brain barrier better than does midazolam.
   - C. Pentobarbital but not midazolam depresses respiratory activity, allowing for better control of pCO_2.
   - D. Pentobarbital at high doses becomes a direct GABA agonist, leading to suppression of neuronal activity independent of endogenous GABA release.

   Preferred response: D

Rationale

Pentobarbital acts on GABA receptors by increasing the duration of chloride channel opening, but at high doses it becomes a direct GABA agonist. Midazolam acts on GABA receptors by increasing the frequency of chloride channel opening and does not act as a direct GABA agonist even at high doses.

4. A global cerebral blood flow (CBF) value of 50 mL/100 g brain/min is normal in which of the following cases?
   - A. A healthy term newborn human
   - B. A healthy 4-year-old child
   - C. A healthy 12-year-old child
   - D. A healthy 20-year-old adult human

   Preferred response: D

Rationale

Normal global CBF for humans from around age 20 to 60 years is approximately 50 mL/100 g brain/min. Normal global CBF for newborns is approximately 40 mL/100 g brain/min. CBF begins to increase from newborn values a few days after birth, peaking around 4 years of age and then declining toward adult values at the end of adolescence.

Chapter 61: Brain Malformations

1. A 12-year-old child with a history of myelomeningocele and hydrocephalus treated with a ventriculoperitoneal shunt is admitted with urosepsis. In addition to dysuria, she has been complaining of headache for several days. Overnight, she becomes increasingly somnolent and difficult to rouse. Which of the following clinical findings are consistent with elevated intracranial pressure from shunt failure?

   A. Absence of papilledema

   B. Enlarged ventricles on computed tomography or magnetic resonance imaging

   C. Inability to look downward

   D. Tachycardia and hypotension

   Preferred response: B

Rationale

Shunt failure and untreated hydrocephalus lead to an accumulation of cerebrospinal fluid in the ventricles, causing them to enlarge in most patients. It is useful to compare new imaging with older studies, as some patients have large ventricles at baseline; relative enlargement compared with old studies is highly concerning for shunt failure. Elevated intracranial pressure from any cause can also lead to papilledema, which is seen on funduscopic examination of the retina. Papilledema may take several days to develop after the intracranial pressure becomes elevated, so its absence should not be interpreted as reassuring in the acute setting. As intracranial pressure continues to rise, pressure on the midbrain can cause an upgaze palsy, also known as Parinaud syndrome. Late in the course, dangerous elevations in intracranial pressure cause brain stem compression, leading to bradycardia and hypertension. Leukocytosis per se is not specific for shunt failure and elevated intracranial pressure, although it can be seen in the setting of shunt infections.

2. A 5-year-old boy is involved in a motor vehicle accident and suffers multiple traumatic injuries to the extremities and abdomen. As part of his trauma workup, a computed tomography scan of the head is performed. This study shows no intracranial hemorrhage but does demonstrate a large cystic structure anterior to the temporal lobe on the right. The brain appears to be displaced slightly by the lesion, and the overlying skull is thinned and protuberant. The family members deny that the boy had experienced headaches or any neurologic problems prior to the accident. The radiologist suggests that this might be an arachnoid cyst. What is the appropriate next step to manage this finding?

   A. Administration of mannitol

   B. Immediate operative decompression

   C. MRI once the patient has been stabilized

   D. Percutaneous needle biopsy to confirm the diagnosis

   Preferred response: C

Rationale

Suspected arachnoid cysts should be imaged with contrast-enhanced MRI to rule out other diagnoses, such as a neoplasm. There is no need to perform this study emergently; it should only be done once the patient is stabilized and his injuries are treated. Indeed, most arachnoid cysts are asymptomatic and are discovered incidentally. The majority never require surgery. Operative intervention can be required when there is hemorrhage into the cyst or when the cyst progressively enlarges, but these circumstances are rare. Although these lesions do tend to displace the brain, they do so chronically and do not cause acute intracranial hypertension; there is no indication for mannitol. Tissue biopsy is not required for the diagnosis, unless the MRI raises concern for an alternative process, such as a neoplasm.

Chapter 62: Neurologic Assessment and Monitoring

---

1. Intracranial pressure (ICP) monitoring has been shown to be most useful in directing therapy in which of the following situations in children?

   A. Hypoxic-ischemic encephalopathy

   B. Diabetic ketoacidosis (DKA) with cerebral edema

   C. Stroke

   D. Traumatic brain injury

   Preferred response: D

Rationale

The most common indication for ICP monitoring in critically ill children is traumatic brain injury (TBI), in which the measurement of ICP directs therapy with the goal of preventing the secondary complications of TBI resulting from cerebral hypoperfusion or metabolic stress. For children with severe TBI, a cerebral perfusion pressure (CPP) between 40 and 65 mm Hg is recommended, and a CPP of 60 to 70 mm Hg is recommended for adolescents. Optimal CPP levels for children younger than 2 years of age have not been established. The benefits and complications of ICP monitoring are unproved for other conditions in which ICP may be increased (eg, DKA, meningitis, metabolic disorders, ALF, stroke, brain tumors, cardiac arrest, hypoxic-ischemic encephalopathy, drowning). Similarly, data on treatment goals of ICP or CPP specific to each insult are lacking.

2. Which of the following statements is correct regarding cranial nerve examination?

   A. Absence of all eye movement with intact pupil light reflex suggests insult to the pons.

   B. Cold caloric stimulation that produces nystagmus with the rapid phase ipsilateral to the ear that has been stimulated indicates intact functioning of the cerebral cortex.

   C. Failure to move only the mouth with preservation of upper face movements

indicates seventh nerve palsy.

D. Roving eye movements are more common with metabolic disorders.

Preferred response: D

Rationale

The pupillary reaction to light is abolished only by structural damage to the midbrain or third cranial nerve. Loss of the pupillary reflexes is always an ominous finding. Preservation of pupillary reflexes in the presence of deep coma suggests a metabolic-toxic cause.

Eye movements are assessed first by observation and then elicited in the patient with depressed mental status by using the doll's head maneuver (oculocephalic response) or cold caloric stimulation (oculovestibular response). In general, coma produced by *metabolic dysfunction* is initially associated with roving, dysconjugate movement and may progress to the cessation of movement. Cold caloric stimulation produces nystagmus with the rapid phase *contralateral* to the ear that has been stimulated. This rapid phase is the equivalent of saccadic eye movements and also indicates intact functioning of the cerebral cortex. The ears are irrigated separately several minutes apart. In comatose patients the fast "corrective" phase of nystagmus is lost and the eyes are tonically deflected to the side irrigated with cold water or away from the side irrigated with warm water. These vestibuloocular responses are lost or disrupted in brain stem lesions. Versive eye deviation is a common finding suspicious for seizures. In this case, the eye deviation is contralateral to the hemisphere with the ictal focus. Alternatively, stroke in the ipsilateral hemisphere may also produce versive eye deviation toward the side of the stroke.

An abnormal corneal reflex may indicate either fifth nerve afferent disease (ipsilateral stimulation results in neither a direct nor consensual eye blink) or seventh nerve efferent disease (ipsilateral stimulation results in a brisk consensual but no direct response).

Unilateral weakness of eye closure, forehead movement, and mouth movement indicates peripheral seventh cranial nerve palsy, whereas failure to move only the mouth with preservation of upper face movements indicates a central corticospinal tract lesion rostral to the pons. Facial weakness may be noted during grimacing while responses to painful stimuli are evaluated. Voluntary pharyngeal and laryngeal control can be tested by asking the patient to say "ah." In the absence of voluntary movement, a hypoactive gag indicates medullary or vagal dysfunction, and a hyperactive gag indicates interruption of corticospinal inhibition to the medulla.

3. Which of the following lesions would most likely explain the presence of a distal pattern of weakness in a child?

A. Lower motor nerve (LMN) injury

B. Myopathic process

C. Neuropathic process

D. Upper motor nerve (UMN) injury

Preferred response: C

Rationale

Acute UMN lesions result in a hypotonic or flaccid pattern of weakness, and in the legs they may be associated with the Babinski sign. In contrast, chronic UMN injury results in a hypertonic limb with associated hyperreflexia. A LMN pattern of weakness is more likely to be associated with a decrease in muscle tone and bulk and decreased or absent reflexes. In general, proximal weakness suggests a myopathic process, whereas a distal pattern of weakness suggests a neuropathy. The precise incidence of ICU-acquired weakness (ICU-AW) is uncertain in children.

4. An 8-month-old boy is admitted to the pediatric intensive care unit from the emergency department after presenting with a focal seizure followed by status epilepticus requiring treatment with two 1 mg/kg doses of lorazepam and a single dose of 20 mg/kg phenytoin, after which he underwent intubation for airway protection. A physical examination shows signs of inflicted trauma with retinal hemorrhages and bruises of different ages. Twelve hours later, the examination is significant for normal vital signs, reactive pupils, and withdrawal to vigorous nailbed pressure. Findings of a computed tomography (CT) scan of the head are normal. Of the following options, which is the best approach for monitoring neurologic function in this case?

   A. Monitor with continuous electroencephalography (EEG) for 12 to 24 hours.

   B. Perform a lumbar puncture.

   C. Perform repeat neurologic examinations with a repeat CT scan of the head if extensor posturing develops.

   D. Perform brain magnetic resonance imaging (MRI) with MR spectroscopy and diffusion-weighted imaging now.

   Preferred response: A

Rationale

The failure of the level of alertness to improve after resolution of clinical seizures should lead to a consideration of nonconvulsive seizures. In this case, although several risk factors exist for increased intracranial pressure following inflicted head trauma, this is less likely based on the presence of normal vital signs, reactive pupils, and withdrawal to pain, in addition to the CT scan. Therefore the next diagnostic study would be an EEG. Prolonged EEG monitoring is preferred because of its greater sensitivity for detecting nonconvulsive seizures. Infection is less likely given the evidence for trauma as the primary etiology. Supratherapeutic phenytoin levels may cause obtundation, but given the patient's history, nonconvulsive seizures are more likely.

5. A 10-year-old boy is struck on the right temple by a car door. He has no loss of consciousness and can recall the event. Four hours later he reports having an occipital headache and a loss of vision in one eye. In the emergency department, he is afebrile with a normal blood pressure and heart rate. During the evaluation he reports having a worsening headache and cannot recall three objects during the mental status examination; acute left-sided weakness develops, and he becomes less responsive. Findings of a head computed tomography (CT) scan are normal, and he is transferred to the pediatric intensive care unit for physiologic

monitoring. Which of the following options is the most appropriate next step in neurologic monitoring?

A. Perform an EEG to evaluate for presence of nonconvulsive seizures.

B. Perform intracranial pressure monitoring.

C. Perform an MRI scan with diffusion-weighted imaging.

D. Perform a CT angiogram of the head with intra- and extracranial vessels.

Preferred response: D

Rationale

This case represents a stroke due to dissection, a mechanism that accounts for 10% to 20% of cases of stroke in the young. The history of trauma followed by an occipital headache suggests a posterior circulation dissection with thalamic stroke. This diagnosis is supported by the symptoms of memory loss and a vision field defect, along with the decline in responsiveness. Findings of the initial head CT scan are normal because the scan was obtained early after the stroke. Confirming the presence of a dissection with a CT angiogram will guide therapy, and anticoagulation will be indicated if the dissection is extracranial and a subarachnoid hemorrhage has been ruled out.

Chapter 63: Neuroimaging

---

1. A 10-year-old child is admitted with subarachnoid hemorrhage (SAH) on computed tomography (CT) and concern for arteriovenous malformation (AVM) is raised. What should be the gold standard exam for ruling out an AVM?

   A. Conventional angiogram

   B. Computed tomography angiogram (CTA)

   C. Magnetic resonance angiogram (MRA)

   D. Ultrasonography

   Preferred response: A

Rationale

CTA is not sensitive for the smallest vascular malformations and does not give temporal information (early venous filling). Magnetic resonance imaging (MRI) will show flow voids from a large malformation, but this is less sensitive than MRA, a CTA, or a catheter angiogram. Though newer techniques can give some temporal information, MRA does not have the same sensitivity as conventional catheter angiogram. A catheter angiogram presently has the best vascular resolution and is most sensitive for early venous drainage, the *sine qua non* of AVM. Ultrasound cannot evaluate for early venous drainage. In addition, it has a limited window, as the anterior fontanelle is closed by this age.

2. A 5-year-old boy is admitted with encephalopathy, with a clinical question of acute disseminated encephalomyelitis (ADEM). What is the most sensitive study to evaluate the brain in this scenario?

A. Computed tomography (CT)

B. Magnetic resonance imaging (MRI)

C. Nuclear medicine

D. Transcranial Doppler

Preferred response: B

Rationale

- MRI with and without contrast is the modality of choice in this scenario.
- Although CT scan is fast and sensitive for many pathologic states, MRI has much greater sensitivity for brain parenchymal lesions.
- Nuclear medicine has limited use in brain imaging currently and is mostly employed to assess for shunt malfunction, CSF leak, and brain death.
- Ultrasonography has a limited window and tissue discrimination and is mostly employed for scanning through open fontanelle for germinal matrix hemorrhage and ventricle size.
- Transcranial Doppler has limited use in brain imaging (eg, sickle cell disease) and vascular spasm (eg, following subarachnoid hemorrhage).

3. A 28-week preemie infant weighing 1200 g has a sudden unexplained drop in hematocrit levels. What does cranial ultrasonography detect best in the premature infant?

A. Acute cerebral ischemia

B. Germinal matrix hemorrhage

C. Small subdural hemorrhage

D. Subarachnoid hemorrhage

Preferred response: B

Rationale

A sudden drop in hematocrit in a premature infant is a cause for concern about the possible development of germinal matrix hemorrhage, because germinal matrix vessels have thin walls and are friable, and these patients frequently lack effective vascular autoregulation. Cranial ultrasonography is useful for the evaluation of the various grades of germinal matrix hemorrhage but is insensitive for evaluating the other forms of intracranial hemorrhage listed. It also is suboptimal in the differentiation of a parenchymal hematoma and a tumor.

4. Left hemiplegia develops in a 3-year-old patient who is known to have Moyamoya disease. What is the most sensitive modality for detecting acute cerebral ischemia?

A. Contrast-enhanced computed tomography

B. Diffusion-weighted magnetic resonance imaging (MRI)

C. T1-weighted MRI

D. Transcranial Doppler

Preferred response: B

Rationale

Anterior circulation cerebral vascular occlusions frequently develop in patients with Moyamoya disease. Diffusion-weighted MRI is the most sensitive and definitive sequence for detecting acute cerebral infarction and parenchymal injury. The affected area is seen as high signal on the diffusion trace image and low signal on the apparent diffusion coefficient map. The other modalities and MRI sequences listed may have supportive roles in diagnosis.

Chapter 64: Pediatric Neurocritical Care

---

1. Which of the following statements is true regarding pediatric neurocritical care?
   A. Evaluation of the impact of neurotherapeutic interventions in children is nearly immediate.
   B. There are no evidence-based guidelines for the treatment of neurologic disorders in children, and treatment is based solely on adult guidelines.
   C. New pharmacologic therapies that target the primary cellular mechanisms of injury in traumatic brain injury are available to the neurointensivist.
   D. There is evidence that a pediatric neurocritical care program can improve survival in patients with traumatic brain injury.

   Preferred response: D

Rationale

Since the previous edition of this text, there is now evidence that a pediatric neurocritical care program can improve survival in an important subset of patients (TBI). To determine whether the time and expense invested in these programs will reduce the neurologic morbidity in pediatric critical illness will require a commitment to long-term care of these patients and the infrastructure to measure these outcomes. This is a substantial challenge.

Evidence based guidelines for several neurologic disorders of children continue to emerge, and effective integration of these guidelines, along with technologic advances, into clinical practice in critically ill children will be an important challenge for clinicians. As examples, (1) the Brain Trauma Foundation published guidelines for management of children after TBI in 2003, and these were revised in 2012; (2) the American Heart Association published guidelines for caring for children after stroke (including the use of antithrombotic therapies); (3) the American Academy of Neurology published a practice parameter to recommend treatment guidelines for children with status epilepticus; and (4) the American Heart Association published guidelines on cardiopulmonary resuscitation and emergency cardiovascular care for children and neonates, which include opinions regarding the neuroprotective strategy of hypothermia. All of these general guidelines have important consequences for caring for the critically ill child, and successful incorporation of these recommendations into clinical protocols within the ICU will be an important

step in optimizing care.

The practice of brain-directed critical care in children faces specific challenges compared to that for adults. First, there are limited data to guide practice. For example, there are no randomized controlled trials to guide management of stroke, cardiac arrest, TBI, or refractory status epilepticus. Second, our understanding of the cellular mechanisms of injury in the developing brain is limited and the process for drug development slow. At present, there are no pharmacologic therapies to the neurointensivist that target the primary cellular mechanisms of injury in (for example) TBI or stroke. Third, the mechanisms of CNS injury in children differ significantly from those in adults, and results of adult studies such as stroke cannot be extrapolated to children. The heterogeneity of disorders in critically ill children that lead to neurologic injury requires that management be based on an understanding of fundamental cell biology and cerebral physiology with little evidence-based medicine to support management decisions. Last, the meaningful (other than survival) impact of any therapeutic interventions in children may take months or years to quantify.

Chapter 65: Coma and Depressed Sensorium

---

1. A 10-year-old male presents with altered mental status. His parents mention that he plays shortstop on the little league baseball team and he was struck in the left side of his head by a foul ball as he stood in the on deck circle waiting to bat. Though dazed, he was initially fine without complaints. The patient's coach, his parents, and emergency medical personnel evaluated him immediately after the injury and found no deficits. The patient's parents were reluctant to go to the emergency room, as he appeared well and no abnormality could be found. His pediatrician was called, and given the reported normal exam and the fact that the patient was wearing a helmet, the pediatrician felt that his parents could watch him closely and report for evaluation should there be any change. Regardless of his exam, the pediatrician requested that the patient be seen in the office the following day. The patient was allowed to sit on the bench during the last two innings of the game.

The patient went to sleep shortly after arriving home. After an hour the parents began to worry and woke him only to find that he would awaken but remained disoriented. As they traveled to the ED, the parents noted that the patient had become less active and more difficult to arouse.

On physical exam, the patient lies still and he awakens to pain, but he never awakens to alertness. A large hematoma is noted above his left ear. The eyes are dysconjugate and the patient has a left-sided ptosis. The left eye is fixed in a downward lateral gaze and the left pupil is dilated and only sluggishly reactive to light. A brisk consensual response is noted in the right eye. The patient's right side is weak and hypertonic. A positive Babinski reflex is noted in the right toe. The patient's eye exam indicates which of the following conditions?

A. A left optic nerve lesion

B. A left oculomotor injury

C. A right optic nerve lesion

D. A right oculomotor injury

Preferred response: B

Rationale

This patient is likely in an *early third nerve phase* of uncal herniation due to an epidural hematoma that occurred as a result of his injury during the baseball game earlier in the day. The patient displays signs of third nerve compression, oculomotor nerve involvement of the eye ipsilateral to the injury, depressed consciousness, upper motor neuron dysfunction, and contralateral weakness. The abnormal gaze and pupillary dilation noted in the left eye are signs of left oculomotor nerve injury. Because the parasympathetic fibers that supply the sphincter pupillae muscles and the motor supply to all the extraocular muscles except the superior oblique (supplied by the fourth cranial nerve) and the lateral rectus (supplied by the sixth cranial nerve) are located peripherally around the third nerve, they are susceptible to early injury due to compression. The result is an eye with a dilated pupil and a fixed gaze that is positioned inferiorly and laterally (“down and out”).

The pupillary light reflect can evaluate the optic nerve (afferent—senses light) and the oculomotor nerve (efferent—pupillary and extraocular motor function). This patient's left pupil has no response to direct light, but his consensual response is intact, suggesting that his motor function is impaired on the left but intact on the right. His ability to sense light is intact on the left. Therefore, the ocular nerve is intact and the patient has an oculomotor nerve defect. In a patient with an acute brain injury, these findings are consistent with brain stem compression.

2. A 15-year-old boy is found unresponsive by a friend at home. He is very bright and until recently has been a straight A student. His parents state that lately he has become a victim of severe hazing and bullying at school. He has a seizure that demonstrates a perfect Jacksonian March. Your suspicion is pseudo seizure after you are told that he spent the summer working with his favorite aunt in her pediatric neurology office. Following the seizure, you place his right hand over his forehead and allow it to drop. It lands hard between his eyes. Which test would most definitively suggest that this patient is not comatose?

   A. A cold caloric test is performed and you notice a slow conjugate deviation of the eyes toward the canal that is irrigated.

   B. A cold caloric test is performed and you notice dysconjugate deviation of the eyes.

   C. A cold caloric test is performed and you notice a slow conjugate deviation away from the canal that is irrigated.

   D. A cold caloric test is performed and you notice fast jerky eye movements back to the midline.

   Preferred response: D

Rationale

In an intact individual, rotational movement of the head produces eye movement of

equal magnitude in the opposite direction. Rotational movements of the head cause the endolymphatic fluid in semicircular canals to stimulate sensors (the ampulla and the cupula) within the inner ear that send excitatory and inhibitory signals to vestibular nuclei that cause the muscular contraction that moves the eyes in the opposite direction. In general, the purpose of the vestibuloocular reflex is to maintain visual stability when the head moves (an advantage for hunters tracking prey).

Both the doll's eye response and caloric testing evaluate the integrity of the vestibuloocular motor response. Although the doll's eye response creates the rotational movement required to initiate movement of endolymphatic fluid in the semicircular canals, changing the temperature within the auditory canal will create similar movement. Therefore, irrigation of the auditory canal with cold or warm water will produce a similar movement of fluid in the semicircular canals.

Cold water instilled in one ear causes endolymph in the ipsilateral semicircular canal to cool and sink, the same movement of endolymph that is created by moving the head away from that ear being irrigated (cold water in the right ear causes the same movement of endolymph in the right semicircular canal as moving the head to the left). As a result, the patient's eye movement is directed away from the cold water. Warm water produces the opposite effect; the endolymph warms and rises within the semicircular canal producing the same fluid movement as moving the head toward the ear being irrigated. The patient's eye movement is directed toward the warm water.

This normal response gives rise to the acronym COWS (cold-opposite, warm-same). But alas, there are no COWS in the ICU; the usual response will not be seen. The irrigation of cold water into the ear of a comatose patient with an intact brain stem will produce a slow conjugate deviation toward the ear being irrigated. An absent or asymmetric response suggests brain stem dysfunction. An intact conjugate response with nystagmus toward the midline is unusual in a comatose patient.

3. A patient presented with a head injury as a result of an automobile crash that occurred 24 hours ago. During the initial evaluation, the patient was difficult to arouse and responsive only to painful stimulation. Further physical examination noted a swelling of the right upper and lower eyelids; the lids could only be retracted with difficulty. The initial radiologic evaluation demonstrated multiple right orbital fractures, an intraorbital hematoma, a small subarachnoid bleed in the left parietal area, and a displaced right humeral fracture. On physical examination this morning, the patient is able to be aroused and follow commands, but he is not moving his right arm. Which statement best describes the extent of the patient's injury?

   A. Brain stem injury is likely because the patient is awake and has a focal neurologic finding.

   B. Central herniation is less likely because the patient was not able to be aroused on presentation and had an eye injury.

   C. Diencephalic and brain stem injury are less likely because the patient has awakened and is following commands.

   D. Medullary and corticospinal tract injury are likely because the patient does not move his right arm.

   Preferred response: C

Rationale

An altered level of arousal is seen in patients who sustain direct brain stem–diencephalic injury to the reticular formation and ascending reticular activating system (ARAS) nuclei or in patients who have bilateral cerebral dysfunction as a result of a diffuse cerebral injury, metabolic injury, or the effects of drugs. Because conscious behavior (ie, the ability to follow commands) depends on the interplay between the cerebral cortex and ARAS, it is unlikely that the patient sustained injury to the diencephalon and brain stem. A patient with significant brain stem injury is unlikely to awaken quickly given the fact that many ARAS structures important to arousal are located in the brain stem. Central herniation causes both diencephalic and brain stem dysfunction, which would be noted by altered mental status, alteration in pupillary function, alteration in the respiratory pattern, and posturing. Uncal herniation classically presents with a unilateral dilated pupil and contralateral hemiparesis. Often mentation is normal in the early stages of uncal herniation. Medullary tract lesions are associated with problems in bulbar muscles such as speech and swallowing. Injury to the corticospinal tract causes hypertonia, but corticospinal tract injury also can cause extensor posturing.

4. The right eye of the patient from the previous scenario appears less swollen on follow-up examination this morning and the lids retract, but the pupillary examination is abnormal. Detailed examination shows anisocoria—that is, the right pupil is larger than the left. The right pupil is nonreactive to direct light, indirect light, and near stimulus. Extraocular movements are not intact, and ptosis is present. Which of the following can best describe the abnormality?

   A. Afferent disorder

   B. Horner syndrome

   C. Sympathetic abnormality

   D. Third nerve palsy

   Preferred response: D

Rationale

The patient's examination is consistent with a third nerve palsy due to traumatic injury. Third nerve palsy is the result of lesions anywhere between the oculomotor nucleus and the extraocular muscles as the nerve follows a long course from the brain stem into the orbit. Given this association, third nerve palsy is often seen in patients with trauma to the orbits. The third nerve innervates the levator muscle of the eyelid, four of the six ipsilateral extraocular muscles (the medial rectus, the superior rectus, the inferior rectus, and the inferior oblique), and the sphincter pupillae (parasympathetic fibers). Patients with third nerve palsy present with ptosis, gaze abnormalities, and varying degrees of pupillary dysfunction (papillary dilation and decreased ability to respond to light). Complete third nerve palsy classically results in an eye that is turned down and out.

Unilateral sympathetic dysfunction and unilateral parasympathetic dysfunction present with anisocoria. If sympathetic dysfunction is present, the small pupil is abnormal. The discrepancy in pupillary size is greater in darkness than in light. Poor pupillary dilation is noted on the abnormal side. If parasympathetic dysfunction is

present, the larger pupil is abnormal. The pupillary size discrepancy is greater in light than in darkness. Poor pupillary constriction is noted on the abnormal side.

Anisocoria is indicative of a lesion in the efferent fibers supplying the pupillary sphincter muscles (dilator pupillae and the sphincter pupillae). Normally pupils are the same size because the efferent limb of the pupillary reflex is bilateral, so that both pupils receive the same command. Lesions in the afferent limb of the pupillary reflex do not produce anisocoria if the consensual pupillary response to light is intact. Afferent pupillary defects are noted when the direct and consensual responses to light are different. Afferent papillary defects are sensitive markers for abnormalities of the afferent limb of the visual pathways.

Horner syndrome occurs as a result of injury to the sympathetic pathway and presents with miosis, ptosis, and anhidrosis. In Horner syndrome, anisocoria occurs and the small pupil is abnormal. A lag in dilation or asymmetry in the speed of dilation is noted in the affected pupil. In children, the most common causes of Horner syndrome are birth trauma, closed head injury, neck trauma, neuroblastoma, and trauma due to surgery.

5. A 5-year-old victim of child abuse presents with bilateral pinpoint pupils reactive to light, apneustic breathing, and decerebrate posturing in response to noxious stimulus. Which of the following is the most likely site of central nervous system injury?

   A. Cortex

   B. Medulla

   C. Midbrain

   D. Pons

   Preferred response: D

Rationale

The supratentorial compartment mainly contains the cortex, thalamus, and other structures above the midbrain. Asymmetric findings on physical examination are indicative of cortical lesions. Given a “focal” or asymmetric examination, hemiparesis suggests a lesion in a contralateral upper motor neuron pathway. Hypotonia, a diminished level of consciousness, and equally reactive pupils are likely to be localized to a cortical lesion on the contralateral side. Acute unilateral cortical lesions often dampen alertness but do not lead to stupor or coma. Expansion of cortical lesions result in raised intracranial pressure, which may reduce blood flow to other areas of the brain and cause the level of consciousness to diminish.

Cortical lesions associated with contralateral thalamic lesions present with contralateral hemiparesis, decorticate (flexor) posturing, a “down and in” gaze deviation (inferiorly and medially), and small reactive pupils. Decorticate posturing (tonic flexion of the upper extremities and tonic extension, adduction, and internal rotation of lower extremities) reflects a lesion above the midbrain. Although not always reliable for localization, posturing suggests that cortical control centers are not functioning.

Midbrain lesions frequently present with hemiplegia contralateral to the lesion and an ipsilateral midposition, nonreactive pupil due to third cranial nerve (CN) palsy. Third CN palsy generally causes both eyes to deviate laterally or inferiorly

and laterally. When gaze is deviated down and out, the patient is said to have *setting sun sign.* Decerebrate or extensor posturing is elicited in response to noxious stimuli in patients with sixth midbrain lesions. This complex yet abnormal response consists of tonic extension of the upper extremities and extension, adduction, and internal rotation of lower extremities.

Contralateral hemiplegia and medial deviation of the ipsilateral eye (CN VI) are hallmarks of medial lesions in the caudal portion of the pons. The ipsilateral pupil remains small and reactive to light. Midline pontine hemorrhages, however, may cause bilateral pinpoint pupils.

Patients with hemiplegia, swallowing difficulties, problems with phonation, nonreactive normal-sized pupils, and normal extraocular eye movements are likely to have an injury to the medulla. CNs VIII to XII exit the brain stem in the area of the medulla. Consequently, medullary lesions are associated with dysfunctional bulbar muscles, such as speech and swallowing. If respiratory centers are affected, apnea may ensue (see Table Q65.5).

6. Injury to which of the following central nervous system sites is responsible for the respiratory pattern seen in a child with Ondine curse?
   A. Cortex
   B. Medulla
   C. Midbrain
   D. Pons

TABLE Q65.5

Clinical Findings Correlated With the Level of CNS Injury

Dysfunction	Response to Noxious Stimuli	Pupils	Eye Position and Movements	Breathing	Motor Findings for Structural Lesions
Both cortices	Withdrawal	Small, reactive	Extraocular movements can be elicited; ipsilateral deviation in frontal lobe lesion	Posthyperventilation apnea or Cheyne-Stokes respiration	
Thalamus	Decorticated posturing	Equal and small, unless the optic tract is also damaged	Eyes deviated down and in toward the side of the lesion	Same as above	Contralateral hemiparesis
Midbrain	Decorticated or decerebrate posturing	Midposition, fixed to light, spontaneous fluctuation	Nystagmus may be present Absent vertical but retained horizontal Loss of ability to adduct; both eyes may be deviated laterally and down in CN III damage	Usually same as above; potential for central reflex hyperpnea	Hemiplegia with contralateral third CN palsy
Pons	Decerebrate posturing	Bilateral pinpoint pupils, reactive to light (especially with midline pontine hemorrhage); Horner syndrome with lateral lesions	Ocular bobbing Absent conjugate horizontal movements with retained vertical movements and accommodation; often eyes are deviated medially, CN VII damage	May exhibit central reflex hyperpnea (Biot), cluster breathing, or apneustic breathing	Hemiplegia with contralateral sixth or seventh CN palsy
Medulla	Weak leg flexion (or none)	Nonreactive, normal size Small Horner syndrome with lateral lesions	Usually no effect on spontaneous eye movements; may interfere with reflex responses, nystagmus	Rarely, ataxic respiration, apnea if respiratory centers involved	Flaccid weakness with difficulty swallowing, phonating, and

					incoordination
Spinal cord	None	Normal reaction, abnormal response if brain stem affected	Normal response	Normal	Flaccid weakness, loss of bowel and bladder control

CN, cranial nerve; *CNS*, central nervous system.

Preferred response: B

Rationale

In Ondine curse, involuntary respiration fails while voluntary respiration is retained. The injury is in the medulla (see Table Q65.6).

7. Which of the following abnormal respiratory patterns indicates a bilateral hemispheric brain lesion?
   A. Apnea
   B. Apneustic respiration
   C. Ataxic respiration
   D. Cheyne-Stokes

TABLE Q65.6

Respiratory Patterns in Patients With Altered Mental Status

Respiratory Pattern	Description	Location of Injury
Posthyperventilation apnea	10 sec of apnea after 5 deep breaths	Bilateral hemispheric dysfunction
Cheyne-Stokes respiration	Rhythmic waxing and waning if respiratory amplitude	Bilateral hemispheric dysfunction
Central reflex hyperpnea	Continuous deep breathing	Bilateral hemispheric dysfunction; injury to lower midbrain or upper pons
Apneustic respiration	Prolonged *inspiratory cramp*	Pons
Ataxic respiration	Infrequent irregular breaths	Lower pons, upper medulla
Ondine curse	Failure of involuntary respiration with retained voluntary respiration	Medulla
Apnea	No respiratory effort	Medulla to C4, peripheral nerves, neuromuscular junction

Preferred response: D

Rationale

TABLE Q65.7

Respiratory Patterns in Patients With Altered Mental Consciousness

Pattern	Description	Localization
Posthyperventilation apnea	Apnea for >10 seconds after 5 deep breaths	Bilateral hemispheric dysfunction
Cheyne-Stokes respiration	Rhythmic waxing and waning of respiratory amplitude	Bilateral hemispheric dysfunction
Central reflex hyperpnea	Continuous deep breathing	Bilateral hemispheric (eg, trauma), lower midbrain, upper pons
Apneustic respiration	Prolonged aspiratory time (*inspiratory cramp*)	Pons
Ataxic respiration	Infrequent irregular breaths	Lower pons or upper medulla
Ondine curse	Failure of involuntary respiration with retained	Medulla

	voluntary respiration	
Apnea	No respiration	Medulla down to C4: peripheral nerves, neuromuscular junction

8. Which of the following is a manifestation of midbrain lesion?
   A. Cheyne-Stokes respiration
   B. Fixed, pinpoint pupils
   C. Inferior and lateral gaze deviation
   D. Ipsilateral hemiplegia
   Preferred response: C

Rationale

Midbrain lesions frequently present with hemiplegia contralateral to the lesion and an ipsilateral midposition, nonreactive pupil due to third CN palsy. Third CN palsy generally causes both eyes to deviate laterally or inferiorly and laterally. When gaze is deviated down and out, the patient is said to have setting sun sign. Decerebrate or extensor posturing is elicited in response to noxious stimuli in patients with sixth midbrain lesions. This complex yet abnormal response consists of tonic extension of the upper extremities and extension, adduction, and internal rotation of lower extremities.

Fixed, pinpoint pupils indicate injury to the pons. Cheyne-Stokes respiration occurs with bilateral hemispheric dysfunction. Swallowing dysfunction indicates injury to the medulla.

Chapter 66: Intracranial Hypertension and Brain Monitoring

1. When intracranial hypertension is more marked in the supratentorial compartment as a result of a unilateral intracerebral hematoma, which of the following observations is true?
   A. The herniation may be more marked anteriorly in the hippocampus.
   B. The temporal lobe on the contralateral side may be displaced into the tentorial notch.
   C. Unilateral transtentorial herniation results from displacement of the affected temporal lobe.
   D. Unilateral transtentorial herniation is evident when there is contralateral third nerve palsy and ipsilateral hemiparesis.
   Preferred response: C

Rationale

When intracranial hypertension is more marked in the supratentorial compartment with an intracerebral hematoma, the temporal lobe on the ipsilateral side, not contralateral side, may be displaced into the tentorial notch. The herniation may be

more marked posteriorly, not anteriorly, in the hippocampus. Herniation is commonly accompanied by displacement of the ipsilateral cingulate gyrus under the falx.

Unilateral transtentorial herniation is evident when there is ipsilateral, not contralateral, third nerve palsy and contralateral, not ipsilateral, hemiparesis.

2. Intracranial pressure (ICP) is being monitored in a child following a closed head injury. Which of the following observations related to ICP values and traces is true?
   A. ICP waves directly related to changes in arterial blood pressure and hyperemic events indicate refractory intracranial hypertension.
   B. In the 30-degree elevated position, a normal ICP value in a healthy, nonmechanically ventilated child is negative with a range of around –5 mm Hg but not exceeding –10 mm Hg.
   C. In the standing upright position, a normal ICP value in healthy children is positive with a range from 5 to 10 mm Hg.
   D. In the horizontal position, a normal ICP value in healthy children is 15 to 20 mm Hg.

   Preferred response: A

Rationale

In the 30-degree elevated position, a normal ICP value in a healthy, nonmechanically ventilated child is positive in relation to atmospheric pressure. In the standing upright position, a normal ICP value in healthy children is negative in relation to atmospheric pressure. In the horizontal position, a normal ICP value in healthy children is in the range of 5 to 10 mm Hg. In normal children, vasogenic B waves and plateau waves in the ICP trace represent abnormal findings. When ICP waves directly relate to changes in arterial blood pressure and hyperemic events, refractory intracranial hypertension is typically present.

Chapter 67: Status Epilepticus

---

1. An 18-month-old male with a history of seizures is transported to the emergency department because he was having generalized tonic-clonic seizures. The parents cannot recall the name of the antiepileptic medication the child is taking. The child took the morning dose and was noted to be febrile to 102°F prior to his nap, for which he received ibuprofen. On arrival the patient is actively seizing. What should be administered next?
   A. Atracurium
   B. Lorazepam
   C. Phenytoin
   D. Phenobarbital

   Preferred response: B

Rationale

The child is presenting in status epilepticus despite being on an antiepileptic drug according to the parents. It is not unreasonable to assume the drug level may not be in the therapeutic range. The recommended first-line treatment for status epilepticus (now defined operationally as seizures lasting more than 5 minutes) is to administer a benzodiazepine. All three benzodiazepines (diazepam, lorazepam, and midazolam) have an onset of action that is less than 5 minutes and enhance inhibitory neurotransmission by binding to a specific benzodiazepine site on the $GABA_A$ receptor. However, diazepam's duration of antiepileptic action appears to be less than 1 hour, making it less attractive than lorazepam. Atracurium in a neuromuscular blocker (NMB) and any NMB that is used to facilitate management of the airway should be short acting. NMBs will mask the motor component of the seizure. The remaining choices are second- (phenytoin) and third-line (levetiracetam and phenobarbital) antiepileptic agents to be considered after one or two doses of benzodiazepines have failed to terminate the seizure.

2. A 12-year-old female is brought into the emergency department for altered behavior according to her parents. She is an honor student at school and her grades have been falling over the past several weeks. While you are examining her, her eyes deviate to the left, her right arm begins to shake, and she develops a full-blown tonic-clonic seizure. Intravenous access is rapidly attained, and after 5 minutes she is given an appropriate dosage of lorazepam. She continues to seize and receives a second dose of lorazepam 10 minutes later followed by an intravenous load of fosphenytoin over 20 minutes. You are arranging to transport her to the PICU when suddenly she begins to have another generalized tonic-clonic seizure and she is given a loading dose of levetiracetam over 20 minutes. Which of the following statements is true?

   A. Effective treatment regimens have been established for this patient.

   B. The risk of complications with refractory status epilepticus (RSE) is the same as that of status epilepticus (SE).

   C. This patient is at risk to have underlying encephalitis.

   D. To meet criteria for RSE, this patient needs to seize continuously for over 3 hours.

   Preferred response: C

Rationale

SE that persists beyond 1 hour despite antiepileptic drug (AED) therapy is considered refractory (RSE). About 30% of SE cases may prove resistant to standard treatment with one of the benzodiazepines and phenytoin. This subgroup of patients has a higher risk of complications, longer hospital stays, and worsened mortality. Most of them have some structural cerebral damage, metabolic disorders, or cerebral hypoxia. Other risk factors include delay in receiving treatment, metabolic encephalopathy, hypoxia, and encephalitis.

Conventional AEDs have low efficacy in RSE, and although conventional AEDs (eg, topiramate, levetiracetam, and carbamazepine) should be continued during this treatment phase, higher dose or higher potency agents are required to abort RSE.

Therapeutic options include high-dose benzodiazepines, barbiturates, propofol, valproic acid, ketamine, lidocaine, and inhalational anesthetic agents. Currently, insufficient evidence exists to conclude which of these high-dose suppressive medications, either alone or in combination, has superior efficacy in the treatment of RSE.

3. A 3-year-old previously well boy is admitted to your intensive care unit following a first episode of febrile status epilepticus. His seizures continue despite appropriate therapy with lorazepam, phenobarbital, phenytoin, and a midazolam infusion. What is the most important reason for requesting continuous electroencephalographic (EEG) monitoring at this time?

   A. To assist in prognostication for the family

   B. To facilitate the detection and treatment of nonconvulsive seizures

   C. To predict the risk for future seizure recurrence

   D. To assist in the evaluation for possible brain death

   Preferred response: B

Rationale

Nonconvulsive seizures commonly occur after convulsive seizures. Antiepileptic drug therapy should be directed at controlling both convulsive and nonconvulsive seizures. Nonconvulsive seizures cannot be detected without an EEG, justifying the request for continuous EEG monitoring in this scenario. EEG also may be used for prognostication and to evaluate the risk for seizure recurrence, but this can be accomplished with a routine 30-minute EEG rather than continuous EEG monitoring. EEG is not useful in monitoring for anticonvulsant adverse effects. EEG is no longer recommended in the evaluation of suspected brain death.

4. A child continues to have generalized tonic-clonic status epilepticus despite receiving two doses of lorazepam delivered by bolus and loading with fosphenytoin. Such prolonged seizures have been associated with impaired neuronal inhibition involving which of the following neurotransmitters?

   A. Acetylcholine

   B. γ-Amino-butyric acid (GABA)

   C. Glutamate

   D. *N*-methyl-D-aspartate

   Preferred response: B

Rationale

Prolonged seizures have been associated with deficits in GABA-mediated neuronal inhibition due to altered $GABA_A$ receptor structure and function and the rapid internalization of synaptic $GABA_A$ receptors. Excitotoxicity resulting from glutamate represents another major mechanism for neuronal injury in persons with status epilepticus (SE). Glutamate is the major excitatory neurotransmitter in the central nervous system (CNS). In addition, both *N*-methyl-D-aspartate (NMDA) and α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid glutamate receptors have

been implicated in the excitotoxicity pathophysiology of persons with SE.

5. Which of the following is the most common cause of status epilepticus in the pediatric population?
   A. CNS infection
   B. Hypoxia
   C. Low levels of acute antiepileptic drugs
   D. Non-CNS infection
   Preferred response: D

Rationale

One of the largest series of SE in children was published in 1970. This review of 239 cases of SE in children identified 47% of cases as symptomatic (26% acute symptomatic and 21% remote symptomatic) and the remaining 53% of cases as idiopathic, including febrile SE. The cause of SE is age dependent; infection plays a larger role in the cause of SE in children. In a 1996 study in Richmond, Virginia, the three major causes of SE in children were infection with fever, remote symptomatic cause, and low anticonvulsant drug levels (Table Q67.5). The three major causes in adults were low antiepileptic drug levels, remote symptomatic cause, and stroke. The cause also differs among younger and older children. Febrile SE and acute symptomatic SE are more common in children younger than 2 years, whereas idiopathic and remote symptomatic causes are most common in older children.

6. During status epilepticus, which of the following ions is responsible for sustaining depolarization of the *N*-methyl-D-aspartate (NMDA) receptors, leading to prolonged excitation?
   A. Calcium
   B. Magnesium
   C. Potassium
   D. Sodium

TABLE Q67.5

Causes of SE in Children From the 1996 Richmond, Virginia, Status Epilepticus Database

Cause	% of Status Epilepticus
Non-CNS infection	52
Remote symptomatic	38
Low antiepileptic drug level	21
Cerebrovascular disease	10
Metabolic	7
Hypoxia	5
Idiopathic	5
CNS infection	2
Drug overdose	2

CNS, central nervous system.

Preferred response: A

Rationale

Prolonged seizures have been associated with deficits in GABA-mediated neuronal inhibition due to altered $GABA_A$ receptor structure and function and the rapid internalization of synaptic $GABA_A$ receptors.

SE causes neuronal injury by both hypoxic-ischemic and excitotoxic mechanisms. The hypoxic-ischemic mechanism involves an increase in neuronal metabolic demand early in SE with a compensatory increase in cerebral blood flow (CBF) and brain oxygenation. Later in SE, these homeostatic mechanisms are unable to keep up with the sustained increase in cerebral metabolic demand. Autoregulation of CBF fails, and consequently a higher mean arterial pressure is required to maintain adequate brain perfusion. As systemic blood pressure falls, a subsequent reduction in brain parenchymal oxygenation occurs. In the face of increased neuronal metabolic demand, uncontrolled muscular contractions, hyperthermia, and impaired airway control, both impaired oxygenation and ventilation contribute to the mismatch between metabolic supply and demand. However, neuropathologic injury occurs even when these systemic factors are controlled and before CBF is reduced, presumably because of unmet neuronal metabolic demands alone.

Excitotoxicity is the second major mechanism for neuronal injury in SE. Glutamate is the major excitatory neurotransmitter in the CNS, and glutamate agonists are used to induce seizures in experimental animal models of SE. Studies have implicated both the NMDA and α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid glutamate receptors in the pathophysiology of SE. The NMDA receptor may have a dual function in the pathophysiology of SE. Magnesium blocks the NMDA channel when it is in its normal state. With depolarization, magnesium no longer blocks the channel, and calcium, which is allowed to flow into the cell, produces further depolarization. Thus the NMDA receptor is activated when the cell is depolarized and responds by further depolarizing the cell, sustaining the excitation. This process has also been implicated in SE-induced neuronal injury, as the accumulation of intracellular calcium activates pathologic processes, resulting in both necrotic and apoptotic cell death.

7. Refractory status epilepticus (RSE) is characterized by seizures that have not responded to first- and second-line therapy and have lasted longer than which of the following?

   A. 15 minutes

   B. 30 minutes

   C. 60 minutes

   D. 120 minutes

   Preferred response: C

Rationale

RSE is characterized by seizures that persist beyond 60 minutes and fail to respond to first- and second-line therapy.

8. Which of the following antiepileptic drugs is associated with the purple glove syndrome?

A. Lorazepam

B. Phenytoin

C. Phenobarbital

D. Propofol

Preferred response: B

Rationale

Phenytoin blocks the fast repetitive firing of neurons through the use-dependent inhibition of voltage-gated sodium channels. Advantages of phenytoin include minimal sedation and respiratory depression at therapeutic levels. The main disadvantage of phenytoin is that it must be infused relatively slowly to minimize the risk of cardiac arrhythmia, infusion site pain, and thrombophlebitis. The maximum recommended infusion rate is 1 mg/kg per minute (maximum, 50 mg/min); therefore an infusion of 20 mg/kg requires 20 minutes. Extravasation of phenytoin at the infusion site has been associated with a so-called purple glove syndrome, which consists of localized extremity edema and discoloration that occasionally requires fasciotomy or amputation. Purple glove syndrome, as well as the more common adverse effects of hypotension and cardiac arrhythmia, is attributed to the fact that phenytoin is dissolved in a solution of propylene glycol and ethanol with a pH of 12.

9. Phenytoin must be infused slowly to avoid which of the following adverse effects?

A. Cardiac arrhythmias

B. Laryngospasm

C. Malignant hyperthermia

D. Respiratory depression

Preferred response: A

Rationale

The main disadvantage of phenytoin is that it must be infused relatively slowly to minimize the risk of cardiac arrhythmia, infusion site pain, and thrombophlebitis.

Chapter 68: Hypoxic Ischemic Encephalopathy: Pathobiology and Therapy of the Postresuscitation Syndrome in Children

---

1. Which ICU-initiated therapy has been shown to improve neurologic outcomes for children surviving cardiac arrest?

A. Maintaining P_aO_2 between 100 to 200 mm Hg immediately

postcardiopulmonary resuscitation

B. Targeted temperature management to 33°C for 72 hours

C. Therapies that maintain intracranial pressure <20 mm Hg

D. To date, there are no proved therapies that improve neurologic outcomes in children who suffered cardiac arrest

Preferred response: D

Rationale

There are prospective randomized controlled trials in neonates to support hypothermia treatment. However, there are no studies to support the use of hypothermia or any of the previously listed therapies to improve neurologic outcomes in children with pediatric cardiac arrest.

2. Which of the following statements is correct regarding pediatric cardiac arrest?

A. Asystole is the initial rhythm associated with the best patient outcomes following cardiac arrest.

B. Fever (temperature >38°C) is associated with poor outcomes after adult but not pediatric cardiac arrest.

C. High arterial blood oxygen levels (>300 mm Hg) post-resuscitation lead to improved outcomes after cardiac arrest.

D. Infants have the highest incidence and worst outcomes among children with out-of-hospital cardiac arrest.

Preferred response: A

Rationale

Asystole as initial rhythm and fever are associated with worse outcomes after pediatric cardiac arrest. The best indicators of outcome are physical exam findings over time in a nonsedated patient. High arterial blood oxygen levels are associated with worse outcomes compared to normoxia, but causation has not yet been proved.

3. Which of the following brain regions can be most vulnerable to hypoxic-ischemic insults?

A. CA1 region of the hippocampus

B. Cerebral cortex layers I and II

C. Occipital lobe

D. Respiratory center in the brain stem

Preferred response: A

Rationale

Certain neurons—such as those in the CA1 region of the hippocampus; cerebral cortex layers III and V; portions of the amygdaloid nucleus; the cerebellar Purkinje cells; and, in infants, periventricular white matter regions and some brain stem nuclei—have long been known to be especially vulnerable to hypoxemic-ischemic insults. Five minutes of complete global brain ischemia produces cell death that

begins to appear between 48 and 72 hours after the insult in these regions, without apparent histologic damage in other brain areas.

4. Which of the following statements regarding global cerebral blood flow and metabolism in the early postresuscitation phase after cardiac arrest is correct?
   A. Cerebral metabolic rate for oxygen ($CMRO_2$) increases immediately following reperfusion.
   B. Cerebral blood flow (CBF) reactivity to $Pa{CO_2}$ remains intact in patients with poor outcome.
   C. Delayed hyperemia is common in patients with good outcome.
   D. Net CBF increases to levels above normal and then decreases.
   Preferred response: A

Rationale

The classic study by Snyder and colleagues on the early postresuscitation period in a dog model of global ischemia showed that after 15 minutes of global brain ischemia, CBF transiently increased to levels well above baseline. Then, after 15 to 30 minutes, CBF progressively decreased to a level below normal for the remainder of the monitoring period (90 minutes). This pattern of "early transient postischemic hyperemia" and subsequent "delayed postischemic hypoperfusion" has been observed almost universally in global cerebral ischemia models including ventricular fibrillation (VF) and asphyxia arrest. The levels of hyperemia and subsequent hypoperfusion vary in relation to the duration of the insult. Although these phases of increased and decreased CBF characterize the net global effect, regional CBF is often inhomogeneous, particularly during postischemic hypoperfusion, when areas of decreased and increased perfusion may coexist. Metabolism, as assessed with $CMRO_2$, is reduced during the early postischemic period and then progressively recovers to a level that varies, depending on the model used and the duration of ischemia.

After global cerebral ischemia, nimodipine may increase CBF during the early postischemic hypoperfusion phase. $CMRO_2$ recovery is generally not increased by treatment. Although nimodipine has been shown to be beneficial in patients after subarachnoid hemorrhage but not ischemic stroke, the testing of strategies targeting early postarrest hypoperfusion deserves further study.

Immediately after cardiac arrest accompanied by restoration of systemic hemodynamic stability, transient global brain hyperemia occurs and is followed by a period of patchy hypoperfusion. The magnitude and duration of these alterations in flow appear to be related to the duration of the insult. In patients with good outcomes, global CBF recovers over the subsequent 24 to 72 hours, and carbon dioxide reactivity remains intact. Patients who do not regain consciousness or progress to brain death have absolute or relative CBF with impaired CO_2 reactivity.

Results from clinical studies of asphyxia arrest are scarce and somewhat conflicting with regard to prognostic implication of high or low values of postarrest CBF on the basis of a single measurement; however, loss of CO_2 reactivity appears to be associated with poor outcome in all studies. Beyda obtained serial measurements of postarrest xenon Xe 133 in a series of children who had asphyxia arrest from

submersion accidents. Children with good neurologic outcomes had slightly decreased CBF values at 12 hours that increased to normal during the subsequent 24 to 60 hours. In these children, CBF reactivity to CO_2 was intact. Children with eventual vegetative outcome or brain death exhibited hyperemia with loss or attenuation of CO_2 reactivity. This hyperemia progressed to low or normal flow during the following 12 to 72 hours in children with vegetative outcome and progressed to low and then no flow with the development of brain death.

5. Which of the following are the most common excitatory amino acid neurotransmitters in the human central nervous system and have a role in neuronal death after a hypoxic injury?

   A. Aspartate and glutamate

   B. Glycine and serotonin

   C. Glutamate and glycine

   D. Serotonin and dopamine

   Preferred response: A

Rationale

Glutamate and aspartate are the major excitatory amino acid neurotransmitters in the mammalian central nervous system, but both also have neurotoxic properties. It has been shown in vitro that hypoxia-induced neuronal death is mediated by synaptic activity. Inhibition of synaptic glutamate release or blockade of glutamate receptors prevented the hypoxic neuronal injury. Glutamate is the major neurotransmitter in the selectively vulnerable zone and accumulates extracellularly in these regions after hypoxic or ischemic insults.

6. Toxic oxygen radical species produced during postischemic reperfusion have been implicated as important contributors to reperfusion injury and delayed cell death. The presence of which of the following is necessary for the production of hydroxyl radical from superoxide ion and hydrogen peroxide (Haber-Weiss/Fenton reaction)?

   A. Calcium

   B. Chloride

   C. Iron

   D. Magnesium

   Preferred response: C

Rationale

- Toxic oxygen radical species of interest in reperfusion injury and delayed cell death after a hypoxic or ischemic event include superoxide anion, hydrogen peroxide, hydroxyl radical, and the reactive nitrogen species peroxynitrite.
- Superoxide anion is produced by the electron transport chain during normal mitochondrial respiration. Mitochondrial dysfunction, as may occur in conditions of ischemia, increases the generation of free radicals that may extend beyond the capacity of endogenous antioxidants, leading to oxidative stress. Superoxide anion

also can be produced as an enzymatic byproduct from the metabolism of arachidonic acid via the cyclooxygenase pathway to form prostaglandins. This phenomenon occurs to a lesser extent via the lipoxygenase and cytochrome P-450 pathways.

- Another source of superoxide anion are neutrophils via neutrophil-reduced nicotinamide adenine dinucleotide phosphate oxidase.
- Xanthine oxidase (XO)-xanthine dehydrogenase (XD) is another potential oxygen radical source. Energy depletion is associated with conversion of adenosine triphosphate to adenosine diphosphate and eventually hypoxanthine. This ischemia- or anoxia-induced energy deprivation also causes conversion of XD to XO via calcium-activated proteases. In the presence of hypoxanthine and oxygen, which become available during reperfusion, XO produces superoxide anion.
- Auto-oxidation of circulating catecholamines or of neurotransmitter catecholamines may represent another potential source of oxygen radicals.
- Another possible contributor to free radical generation is delocalized iron. Iron is normally transported in the blood tightly bound to transferrin and stored inside the cell bound to ferritin. In ischemic conditions with accompanying acidosis, however, iron may be displaced from its normal binding sites and can catalyze reactions that promote oxygen radical formation. Most commonly implicated is the Haber-Weiss/Fenton reaction, whereby the potent hydroxyl radical is produced from superoxide anion and hydrogen peroxide in the presence of free iron.
- Nitric oxide is another free radical that contributes to both nitrosative and oxidative stress.

7. Which of the following worsens neuronal injury after a hypoxic insult?

   A. Activation of nitric oxide synthase

   B. Blockade of glutamate receptors

   C. Induction of heat shock proteins

   D. Up-regulation of the bcl-2 gene

   Preferred response: A

Rationale

Nitric oxide is another free radical that contributes to both nitrosative and oxidative stress. Nitric oxide increases during ischemia through *N*-methyl-D-aspartate receptor stimulation, mediated by the release of excitatory amino acids and subsequent calcium-mediated activation of neuronal nitric oxide synthase. Nitric oxide, in the presence of superoxide, produces peroxynitrite. Free radicals have also been associated directly with an increased release of excitatory amino acids and vice versa. Not only do they participate in each other's release and formation, but they may act synergistically in causing tissue damage.

In response to the complex sequence of pathobiological events that evolve after brain injury, several *endogenous neuroprotectants* are produced, induced, or activated after ischemia, and their postulated or proved functions improve cell (specifically neuronal) survival in in vivo and in vitro models.

The heat shock proteins are one family of candidate neuroprotectants that are highly conserved among biological species and are induced in cells after a variety of stimuli. Thermal stress is the classic example; however, any insult that damages protein structure, including ischemic and traumatic brain injury, can produce a heat shock protein response.

Another potential mechanism for endogenous neuroprotection is the up-regulation of genes that inhibit programmed cell death. The mammalian gene bcl-2, a proto-oncogene, can block apoptotic cell death and perhaps necrotic cell death as well. The bcl-2 gene is expressed in neurons surviving both focal and global ischemia and is reduced in degenerating neurons after cardiopulmonary arrest in rats.

Adenosine is an endogenous biochemical mediator that may serve a protective role after cerebral ischemia, particularly early after injury. Adenosine is increased in brain tissue after experimental ischemia and in response to hypoxia, hypotension, and hypoglycemia. The beneficial effects of adenosine after ischemia include improved regional blood flow, reduced local oxygen demand, attenuation of both excitotoxicity and calcium accumulation, and antiinflammatory and rheologic effects.

Pioneering studies by Rothman and colleagues demonstrated in vitro that hypoxia-induced neuronal death is mediated by synaptic activity. Inhibition of synaptic glutamate release or blockade of glutamate receptors prevented hypoxia-induced neuronal injury. Glutamate is the major neurotransmitter in the selectively vulnerable zones and accumulates extracellularly at supraphysiologic levels in these regions after hypoxic or ischemic insults.

8. Abnormal levels of which of the following in the cerebrospinal fluid (CSF) of victims of cardiopulmonary arrest are most predictive of poor outcome?

A. Aspartate

B. Glutamate

C. Glycine

D. S-100B

Preferred response: D

Rationale

Adjunctive prognostic information can be derived from brain-derived protein levels in serum or CSF. High serum levels of neuron-specific enolase (NSE) in comatose patients at 24 and 48 hours after cardiopulmonary arrest predict poor neurologic outcome. Martens and colleagues found that serum concentrations of the astrocyte-derived protein S-100B were superior to serum NSE (as well as CSF S-100B and NSE) in predicting which adult patients would regain consciousness after cardiac arrest. A study used a multimodal approach, combining serum concentrations of NSE, the astrocyte-derived protein S-100B, and somatosensory-evoked potentials prospectively in 27 adult patients after cardiac arrest, and was able to predict all patients who did not regain consciousness. Serum NSE is increased in children after cardiac arrest and peaks at 24 hours. NSE and other biomarkers may be useful in determining responsiveness to therapeutic interventions; for example, it has been reported that decreasing serum NSE occurs mainly in hypothermic (versus normothermic) adults after cardiac arrest and is predictive of outcome. Other

biomarkers showing promise in case series are procalcitonin, alpha II-spectrin breakdown products, serum glial fibrillary acidic protein, and brain natriuretic peptide.

9. Which of the following is the most reliable predictor of outcome in children after cardiac arrest?
   A. Brain magnetic resonance imaging with spectroscopy performed on day 7 after cardiopulmonary arrest
   B. Neurologic examination of the patient on day 21 after cardiopulmonary arrest
   C. Serum levels of neuron-specific enolase on day 1 after cardiopulmonary arrest
   D. Somatosensory-evoked potentials performed on day 7 after cardiopulmonary arrest
   Preferred response: B

Rationale

Although all of the aforementioned tests have predictive value in terms of patient prognosis after cardiac arrest, the neurologic examination in the absence of sedating medications remains the most reliable.

Chapter 69: Pediatric Stroke and Intracerebral Hemorrhage

---

1. Which of the following is not a risk factor for childhood arterial ischemic stroke?
   A. Cerebral arteriopathy
   B. Cyanotic congenital heart disease
   C. Routine immunizations
   D. Sickle cell anemia
   Preferred response: C

Rationale

Routine immunizations may be protective against childhood AIS.[1]

2. What is the most common cause of intraparenchymal intracranial hemorrhage in childhood?
   A. Arteriovenous malformation
   B. Cerebral cavernous malformation
   C. Coagulation abnormality
   D. Tumor
   Preferred response: A

Rationale

Arteriovenous malformation (AVM) accounts for approximately half of childhood

intraparenchymal ICH.

3. Regardless of etiology, the management of arterial ischemic stroke (AIS) should focus on specific priorities. Which of the following is *not* considered a focus of such management?
   A. Hyperventilation
   B. Neuroprotection
   C. Optimization of perfusion
   D. Prevention of recurrence
   Preferred response: A

Rationale

Regardless of the etiology of AIS, management should focus on optimizing perfusion and oxygenation, neuroprotection (minimizing expansion of the ischemic core and secondary injury and rescuing the penumbra), rehabilitation, and prevention of recurrence.

4. Which of the following medications is used mostly in the context of clinical trials in the management of pediatric arterial stroke?
   A. Aspirin
   B. Low-molecular-weight heparin
   C. Recombinant tissue plasminogen
   D. Unfractionated heparin
   Preferred response: C

Rationale

Aspirin, low-molecular-weight heparin, unfractionated heparin, and warfarin are commonly used medications for anticoagulation in children with arterial ischemic stroke. Recombinant tissue plasminogen activator has not been extensively studied in the pediatric population and is used mainly in the context of clinical trials.

Chapter 70: Central Nervous System Infections and Related Conditions

---

1. A 13-year-old boy who resides in Tennessee recently returned from a fishing and swimming vacation to northeast Florida. Five days prior to presentation, he began complaining of a strange taste in his mouth, sore throat, and headache. He

presented to the emergency department with fever to 102.4°F, hallucinations, and ataxia. He has a right sixth nerve palsy but is currently protecting his airway and is intermittently able to follow commands. Acyclovir, intravenous immunoglobulin, and meningitic dose antibiotics fail to improve his encephalopathy. On the seventh day of his admission to the pediatric ICU, he develops status epilepticus and requires endotracheal intubation. Which of the following treatments should be instituted immediately?

A. Glycerol, metronidazole, and dexamethasone

B. High-dose acyclovir and dexamethasone

C. Intravenous and intrathecal amphotericin, azithromycin, fluconazole, rifampin, miltefosine, and dexamethasone

D. Plasmapheresis followed by high-dose corticosteroids and intrathecal methotrexate

Preferred response: C

Rationale

Primary amebic meningoencephalitis (PAM) is a rare, often fatal disease most commonly caused by infection with *Naegleria fowleri,* a thermophilic, free-living ameba found in freshwater environments. In the United States, *N. fowleri* is commonly found in warm freshwater environments in 15 southern-tier states (Arizona, Arkansas, California, Florida, Georgia, Louisiana, Mississippi, Missouri, Nevada, New Mexico, North Carolina, Oklahoma, South Carolina, Texas, and Virginia). *Naegleria* species typically cause PAM in children and healthy adults who have been swimming in infected water. *N. fowleri* enter through the olfactory neuroepithelium at the level of the cribriform plate and invade the submucosal nervous plexus. Symptoms begin after a 3- to 7-day incubation period. PAM presents in a manner similar to acute bacterial meningitis, but physicians often miss the diagnosis initially. History is vital for making the diagnosis. Recent exposure to diving, swimming, or splashing in warm freshwater should suggest the possibility of amebic meningoencephalitis. Prompt examination of the cerebrospinal fluid for *N. fowleri* is fundamental to establishing this diagnosis. The onset of PAM is abrupt but nonspecific. Patients may complain of sore throat, headache, nausea, vomiting, malaise, and fever. Early findings may also include irritability, hallucinations, meningismus, cerebellar ataxia, and cranial nerve palsies, although focal neurologic defects are usually absent. Alterations in taste and smell may occur, likely due to involvement of the olfactory nerve. The diagnosis is made by examination of centrifuged CSF wet mounts for motile trophozoites. However, failure to visualize these amebas does not exclude PAM. The diagnosis is often missed when *Naegleria* organisms are mistaken for atypical leukocytes, specifically monocytes or lymphocytes. Based on the treatment regimens used in the most recent survivors of PAM, the CDC currently recommends the following drug therapy in CNS infections caused by *Naegleria fowleri* as well as *Balamuthia mandrillaris* and *Acanthamoeba* species: (1) IV amphotericin B, (2) intrathecal amphotericin B, (3) azithromycin, (4) fluconazole, (5) rifampin, (6) miltefosine, and (7) dexamethasone.

2. Five days after a viral upper respiratory tract infection, a previously healthy 7-year-old boy is admitted to the intensive care unit with fever and encephalopathy.

After a computed tomography scan shows no space-occupying lesion or signs of elevated intracranial pressure, a lumbar puncture is performed, and it shows normal opening pressure, 20 WBC/hpf, 90 mg/dL protein, and no organisms on Gram stain. Herpesvirus PCR is negative. T2-weighted magnetic resonance images show several large asymmetric lesions of high signal intensity in the deep cortical gray and subcortical white matter. EEG demonstrates diffuse slowing but no epileptiform activity. Which treatment is most likely to be beneficial in this case?

A. Acyclovir

B. Ceftriaxone

C. High-dose methylprednisolone

D. Metronidazole

Preferred response: C

Rationale

This patient is presenting with signs and symptoms of acute disseminated encephalomyelitis (ADEM). ADEM is an immune-mediated process that may result in a clinical picture similar to infectious meningitis or encephalitis. MRI typically demonstrates large, bilateral, poorly demarcated lesions in white matter and deep cortical gray structures. First-line treatment for ADEM includes high-dose corticosteroids, typically methylprednisolone, followed by a taper over several weeks. Although prophylactic antibiotics such as acyclovir, ceftriaxone, vancomycin, or metronidazole are often administered while awaiting the results of cultures and ancillary studies, the child in this scenario is most likely to benefit from treatment with methylprednisolone.

3. A 1-year-old child is admitted to the pediatric intensive care unit with signs and symptoms of meningitis. Dexamethasone has been shown to improve survival in meningitis because of which of the following etiologic agents?

A. Drug-resistant pneumococcus

B. Herpesvirus

C. *Mycobacterium tuberculosis*

D. *Neisseria meningitidis*

Preferred response: C

Rationale

Meta-analysis and retrospective studies have demonstrated beneficial effects in *Hemophilus influenzae* type b and pneumococcal meningitis. However, this conclusion was made at a time when drug-resistant *Streptococcus pneumoniae* was not a serious problem. The data could support a beneficial effect in *H. influenzae* type b meningitis, but because this organism is an uncommon pathogen at this time, empiric therapy would not be warranted in most cases. In the era of drug-resistant *S. pneumoniae,* where an isolate may be resistant to the third-generation cephalosporins, it has been suggested that dexamethasone (DXM) may impair the diffusion of vancomycin through the blood-brain barrier, delaying cerebrospinal fluid sterilization. Thus caution has merit. Some clinicians recommend the addition of rifampin under these

circumstances. Further studies are needed in this patient population. Lastly, because maximal beneficial effect would be gained by administering DXM prior to antibiotic therapy, previously treated infants and children should not receive DXM.

No evidence exists that corticosteroids are beneficial in patients with viral or meningococcal or neonatal meningitis. In contrast, patients with tuberculous meningitis treated with steroids have an improved survival compared with nonrecipients. However, the severity of disability commonly observed with tuberculous meningitis is not altered.

4. Which of the following results of a cerebrospinal fluid (CSF) examination is affected the most with the prior use of oral antibiotics?

   A. CSF glucose level

   B. CSF protein level

   C. Gram stain

   D. Neutrophil count

   Preferred response: C

Rationale

In most instances, prior oral antimicrobial therapy will not significantly alter CSF cell counts, differential, and chemistries in children with bacterial meningitis. In contrast, Gram stain and culture positivity are greatly reduced.

5. A 3-year-old child presents to the hospital in July with seizures, fever, meningeal signs, cranial nerve involvement, and speech impairment. Cerebrospinal fluid analysis is suspect for a viral etiology. Which of the following is the most likely agent of this child's meningoencephalitis?

   A. Arbovirus

   B. Epstein-Barr virus

   C. Herpesvirus

   D. Varicella-zoster

   Preferred response: A

Rationale

The enteroviruses and arboviruses in particular display seasonality in infection and are seen most frequently in the summer and autumn months. Herpesviruses, cytomegalovirus, varicella-zoster, and Epstein-Barr virus often show a predilection for the winter and spring. Herpes simplex, however, does not demonstrate any seasonality. With this epidemiology in mind, the evaluation of children with suspected viral meningoencephalitis is guided by many factors including age, geographic location, season of the year, vaccination status, chronic conditions or immunosuppression, history of tick or mosquito exposure, and travel history.

6. Which of the following is the most common presentation of herpesvirus (HSV) encephalitis in a newborn?

   A. Fever

   B. Nuchal rigidity

C. Seizures

D. Skin lesions

Preferred response: C

Rationale

Neonates presenting with encephalitis due to HSV often do not demonstrate fever. The most common presenting signs for neonates with HSV central nervous system disease are seizures and lethargy. Skin lesion findings are variable. Infants with HSV infection also may have disseminated disease, which increases the morbidity and mortality significantly.

7. A 9-year-old boy and his 12-year-old cousin present with similar signs and symptoms of sore throat, headache, nausea, and vomiting a few days after swimming in a lake in Texas. On physical examination, both children are irritable and have meningeal signs and ataxia. Which of the following is the most likely etiologic agent in these cases?

A. Herpes simplex virus type 1

B. *Mycobacterium tuberculosis*

C. *Naegleria fowleri*

D. *Toxoplasma gondii*

Preferred response: C

Rationale

Primary amebic meningoencephalitis (PAM) is a rare, often fatal disease caused by infection with *N. fowleri*, a thermophilic, free-living ameba found in freshwater environments. *N. fowleri* is the causal agent of most PAM infections, but other species of *Naegleria* having pathogenic potential have been described (*Naegleria australiensis* and *Naegleria italica*). The habitat for *N. fowleri* is natural or man-made freshwater lakes or an inadequately chlorinated swimming pool where the amebas can feed on bacteria and proliferate. In the United States, *N. fowleri* is commonly found in warm freshwater environments in 15 southern-tier states (Arizona, Arkansas, California, Florida, Georgia, Louisiana, Mississippi, Missouri, Nevada, New Mexico, North Carolina, Oklahoma, South Carolina, Texas, and Virginia).

The onset of PAM is abrupt, with sore throat, headache, nausea, vomiting, malaise, and fever. Early findings also may include irritability, hallucinations, meningismus, cerebellar ataxia, and cranial nerve palsies, although focal neurologic defects are usually absent. Alterations in taste and smell may occur, likely because of involvement of the olfactory nerve.

Symptoms begin after a 3- to 7-day incubation period. PAM presents in a manner similar to acute bacterial meningitis, but physicians often miss the diagnosis initially. History is vital for making the diagnosis. Residence or travel to a southern-tier state in the United States must be verified. Recent exposure to diving, swimming, or splashing in warm freshwater should suggest the possibility of amebic meningoencephalitis and prompt examination of the CSF for *N. fowleri*. Differential diagnosis includes acute bacterial meningitis, herpes simplex virus-1 encephalitis, and viral or fungal meningitis. With immunosuppressed patients, amebic meningitis

might be confused with toxoplasmosis, cytomegalovirus infection, and other opportunistic pathogens. The diagnosis is made by examination of CSF wet mounts for motile trophozoites; however, failure to visualize these amebas does not exclude PAM. The diagnosis is often missed when *Naegleria* organisms are mistaken for atypical monocytes or lymphocytes.

Chapter 71: Acute Neuromuscular Diseases and Disorders

---

1. A 10-year-old boy presents to the hospital after 3 weeks of progressive symmetric leg weakness, which is better in the morning and worsens throughout the day, accompanied by bilateral ptosis. The emergency room finds him to have rapid, shallow breathing and absent reflexes. After he walks, he becomes too weak to climb back into his hospital bed. After stabilizing his respiratory status, which is the most appropriate next step?

   A. AChR antibody testing before treating

   B. Edrophonium challenge

   C. Intravenous immunoglobulin

   D. MRI spine

   Preferred response: B

Rationale

The patient clinically appears to have myasthenia based on the ptosis, easily fatigable weakness, and rapid and shallow breathing. An edrophonium challenge can quickly confirm the diagnosis. Although some patients with mild symptoms may have antibody testing as part of their diagnostic workup before treatment, this patient's clinical status is too severe to withhold treatment pending those results. After an edrophonium challenge, treatment can begin. MRI of the spine would not explain the ptosis.

2. A 6-month-old baby presents to the emergency room after progressive descending weakness. The parents feel the baby developed constipation a couple of weeks ago. You notice decreased respiratory drive, weak cry, profound hypotonia and weakness, and absent reflexes. The child has no history of fever or other signs of illness. Nerve conduction testing and EMG are not readily available. Besides supportive care, what is the next most appropriate step?

   A. Administer human botulism immune globulin before confirmatory testing.

   B. Begin intravenous immunoglobulin (IVIG); no confirmatory test is needed.

   C. Order stool culture for botulism and await results before further treatment.

   D. Start plasmapheresis.

   Preferred response: A

Rationale

This patient's history and physical strongly suggest botulism. A stool culture may show botulism, but, because of the constipation, the test results may take too long to come back to be helpful. The test may still be helpful to confirm but should not delay treatment. Human botulism immune globulin has been shown to speed improvement and lead to shorter hospital stays. This has not been shown with IVIG.

3. An infant presents to the pediatric intensive care unit with hypotonia, poor suck, hypoventilation, and impaired swallowing. Subsequently the child is diagnosed with botulism. A culture of a catheterized urine specimen indicates growth of a gram-negative rod at 10^6 colonies per mL of urine. In addition, a ventilator-associated pneumonia, involving a gram-positive coccus in clusters and abundant neutrophils obtained from a protected bronchial brush specimen, is diagnosed. In this setting, which of the following antimicrobial agents specifically should be avoided?
   A. Ampicillin
   B. Azithromycin
   C. Cefuroxime
   D. Gentamicin
   Preferred response: D

Rationale

Aminoglycosides will exacerbate any neuromuscular blockade and their use should be avoided in persons with botulism.

4. Which of the following statements concerning Guillain-Barré syndrome (GBS) is true?
   A. Cerebrospinal fluid (CSF) findings in the first week include decreased levels of protein.
   B. GBS typically presents with a progressive paralysis limited to the lower extremities.
   C. Sphincter disturbances occur frequently in the course of GBS.
   D. Steroids do not help hasten the recovery of persons with GBS.
   Preferred response: D

Rationale

The neurologic symptoms of GBS typically present with progressive paralysis that is relatively symmetric and may evolve to all extremities. Other symptoms include varying degrees of hyporeflexia or areflexia, or even respiratory embarrassment. Other presentations include acute ataxia, pain, or cranial neuropathies. In one study, risk factors for patients requiring ventilation included cranial nerve involvement, elevated CSF protein during the first week of illness, and a short period between antecedent illness and onset of symptoms. Sphincter disturbances rarely occur early in the course of GBS and are usually transient. Autonomic symptoms that may be overlooked also are present in some cases. Autonomic instability, particularly cardiac arrhythmias, increases the morbidity of this disease.

Per criteria established by Asbury and Cornblath, the features that are required for

the diagnosis include progressive motor weakness of more than one limb and areflexia. Symptoms that are strongly supportive of GBS include the relative symmetry of symptoms, mild sensory symptoms, cranial nerve involvement, autonomic symptoms, and recovery that usually begins 2 to 4 weeks after symptom progression discontinues.

Steroids do not hasten the recovery of persons with GBS. If the symptoms are severe, treatment options for GBS include plasmapheresis and intravenous immunoglobulin (IVIG). In 2003 the American Academy of Neurology published a practice parameter after reviewing the adult literature and made several recommendations. First, plasmapheresis and IVIG both hasten recovery, and neither is more efficacious. Using these two treatments sequentially is not superior to use of either treatment alone.

5. Which of the following findings are a part of the criteria for the diagnosis of dermatomyositis?

   A. Decrease of aldolase

   B. Decreased and low-frequency discharges on an electromyogram

   C. Heliotrope rash

   D. Symmetric distal weakness

   Preferred response: C

Rationale

Five major criteria are described for the diagnosis of dermatomyositis: (1) symmetric proximal weakness is present, which may include respiratory muscles; (2) the dermatologic criterion includes the heliotrope rash and the Gottron sign in addition to a scaly erythematous rash over the joints, face, neck, and upper torso; (3) elevated creatine phosphokinase and aldolase are laboratory criteria; (4) muscle biopsy discloses evidence of necrosis of type I and II fibers, phagocytosis, and inflammatory exudates; and (5) the electromyographic criteria in dermatomyositis are consistent with an inflammatory myopathy revealing spontaneous activity, myopathic motor units, and bizarre high-frequency repetitive discharges.

6. Which of the following is the most common cause of acute flaccid paralysis in children?

   A. Botulism

   B. Guillain-Barré syndrome

   C. Myasthenia gravis

   D. Tick paralysis

   Preferred response: B

Rationale

Guillain-Barré syndrome (GBS) is the most common cause of acute flaccid paralysis in children. The incidence is estimated to be 0.38 to 1.1 per 100,000 in a population younger than 15 years. Other causes of acute flaccid paralysis in the pediatric population include botulism, tick paralysis, periodic paralyses, and organophosphate poisoning.

7. A 3-year-old child presents to the PICU with a 1-week history of inactivity and bilateral lower extremity weakness accompanied by numbness. Three weeks prior to exhibiting these symptoms, he had gastroenteritis that has since resolved. On physical examination, you notice an absence of reflexes in lower extremities and a weak gag reflex. The patient looks lethargic. You perform a spinal tap. Which of the following is the *most likely* result of the spinal tap?

A. Albuminocytologic dissociation

B. Decrease in glucose in CSF

C. Lymphocytosis in CSF

D. Presence of gram-negative bacteria on Gram stain

Preferred response: A

Rationale

The most common acute neuromuscular disease to present to the intensive care unit is Guillain-Barré syndrome. When given the history of an ascending paralysis, a clinician can easily place GBS in the differential diagnosis; however, this history may be difficult to obtain, particularly if the patient is a small child or an infant. A prodromal respiratory or gastrointestinal illness is commonly found in the history. The prodromal illnesses may include *Campylobacter jejuni* and cytomegalovirus.

The neurologic symptoms typically present with progressive paralysis that is relatively symmetric and may evolve to all extremities. Other symptoms include varying degrees of hyporeflexia or areflexia or even respiratory embarrassment. Other presentations may include acute ataxia, pain, or cranial neuropathies. In one study, risk factors for patients requiring ventilation included cranial nerve involvement, elevated CSF protein during the first week of illness, and a short period between antecedent illness and onset of symptoms.

Diagnostic studies include examination of the CSF and nerve conduction studies. The CSF reveals an elevated protein level amid a relative paucity of white blood cells, usually less than 10 cells/mL, with the protein increasing after the first week of symptoms. Electrodiagnostic testing reveals motor conduction velocities in the demyelinating range, conduction block, temporal dispersion, and prolonged F waves.

8. The child described in the scenario for question 7 becomes progressively weaker, requiring endotracheal intubation and mechanical ventilation. After 3 days on mechanical ventilation, the child continues to require ventilatory support, and autonomic instability with hypotension and cardiac arrhythmias has developed. Besides monitoring and support in the PICU, which other modality of treatment should be initiated in this case?

A. Extracorporeal membrane oxygenation

B. Intravenous immunoglobulin

C. Leukapheresis

D. Systemic corticosteroids

Preferred response: B

Rationale

If the symptoms are severe, treatment options for GBS include plasmapheresis and intravenous immunoglobulin (IVIG). In 2003 the American Academy of Neurology published a practice parameter after reviewing the adult literature and made several recommendations. First, plasmapheresis and IVIG both hasten recovery, and neither is more efficacious. Using these two treatments sequentially is not superior to use of either treatment alone. Finally, steroids do not seem to help. The decision of which therapy to apply to children is controversial because a large randomized study has not been performed. Plasmapheresis may be technically difficult to perform in young or very small children; therefore, immunoglobulin may be used with more ease. Results from one adult study in which the two methods were compared showed that 53% of the patients treated with immunoglobulin improved by one or more grades on the functional scale at 4 weeks compared with 34% of the patients treated with plasmapheresis. Favorable improvement in pediatric patients treated with immunoglobulin has been reported in several small series. More recently, a randomized trial in children showed that fewer relapses occurred if 2 g/kg of IVIG were divided over 5 days instead of 2 days. If additional courses of IVIG are necessary, a 2-day protocol is often well tolerated.

9. A previously healthy 8-year-old boy presents to the emergency department in May with complaints of acute onset of weakness in his arms and legs over the previous day and sensation of “pins and needles” in his legs. He is unable to get up without assistance. The patient is alert, has normal vital signs, and is afebrile. Neurologic examination detects the inability to lift his head from the supine position, decreased muscle strength and absent muscle stretch reflexes in upper and lower extremities, bilateral ptosis, and lateral rectus muscle paresis. Findings of an erythrocyte sedimentation rate and cerebrospinal fluid (CSF) examination were normal. What is your presumed diagnosis?

   A. Botulism

   B. Guillain-Barré syndrome

   C. Myasthenia gravis

   D. Tick paralysis

   Preferred response: D

Rationale

The clinician must always entertain tick paralysis in the differential diagnosis of acute flaccid paralysis in children. Affected patients are usually between the ages of 1 and 5 years. A female preponderance exists (76%), presumably because of longer hairstyles among girls. The ticks most often implicated in North America are *Dermacentor andersoni* (wood tick) and *Dermacentor variabilis* (dog tick). Cases in North America typically occur from April to June, when the adult ticks emerge from hibernation to seek hosts.

The cause of the symptoms is a neurotoxin that is secreted in the saliva of the gravid female tick. This neurotoxin inhibits the release of acetylcholine at the presynaptic terminal. The symptoms begin with vague complaints of fatigue, irritability, and pain. Vague symptoms may not begin until approximately 5 days after tick attachment, but they progress rapidly. Other symptoms include ataxia. If the tick remains attached, a symmetric ascending paralysis with areflexia develops.

Subsequently, cranial nerve symptoms of bulbar and facial weakness and respiratory involvement occur. No systemic features are seen in tick paralysis. Patients are afebrile with normal vital signs, erythrocyte sedimentation rate, CSF, and mental status. The removal of the tick results in the rapid reversal of symptoms, usually within 24 hours.

10. What statement is correct regarding response to therapy in the patient described in the previous scenario?

A. Anticholinesterase medications are the mainstay of therapy.

B. Intravenous immunoglobulin (IVIG) should be initiated immediately.

C. Plasmapheresis is the preferred modality of treatment.

D. Removal of the tick should result in a rapid reversal of symptoms.

Preferred response: D

Rationale

In a patient with tick paralysis, removal of the tick should result in a rapid reversal of symptoms, usually within 24 hours. The tick is removed with blunt curved forceps or tweezers. The tick should be grasped at the point of attachment, as close to the skin as possible, and then pulled upward with steady pressure. Twisting or jerking motions may cause parts of the tick to break off, particularly the mouthparts. The tick should not be handled with bare hands. Needham evaluated various methods of tick removal including fingernail polish, petroleum jelly, 70% isopropyl alcohol, and a hot kitchen match. None of these passive techniques induced tick detachment.

Anticholinesterase medications such as pyridostigmine bromide (Mestinon) are utilized for the treatment of myasthenia gravis. Plasmapheresis and IVIG play a role in the treatment of myasthenic crisis and acute exacerbations of myasthenic symptoms, as well as more severe cases of GBS with autonomic manifestations.

11. What adverse effects should you monitor for during an edrophonium challenge in a patient with myasthenia gravis (MG)?

A. Bradycardia and bronchospasm

B. Hypertension and bradycardia

C. Hypotension and increased fatigability

D. Tachycardia and hypertension

Preferred response: A

Rationale

When a patient is suspected to have MG, the best diagnostic bedside test is the edrophonium (Tensilon) challenge. Edrophonium is an intravenous short-acting anticholinesterase preparation. The dosing in infants is 0.15 mg/kg, and the dosing is 0.2 mg/kg in older children. Only 10% of the entire dose is given initially so the clinician can observe for muscarinic adverse effects. Atropine (0.015 to 0.04 mg/kg) should be available for these possible adverse effects, which include bradycardia and respiratory distress resulting from bronchial secretions and bronchospasm. After the trial dose is tolerated, the entire dose is then given. The patient should be observed

during the trial for changes in ptosis or fatigability. The onset of action is approximately 30 to 90 seconds after intravenous push and remains for approximately 5 minutes.

12. Which of the following symptoms will persist after the administration of atropine in a patient with organophosphate poisoning?
   A. Bradycardia
   B. Diarrhea
   C. Muscle weakness
   D. Salivation
   Preferred response: C

Rationale

In both organophosphate and carbamate poisoning, atropine is used as an antidote for muscarinic symptoms (ie, miosis, excessive salivation, sweating, diarrhea, urination, and bradycardia). Treatment with atropine, however, does not reverse the nicotinic symptoms, which include muscle weakness or respiratory failure. Atropine should be administered as quickly as possible and in adequate doses. In children older than 12 years, the dosing is 1 to 2 mg intravenously every 10 to 30 minutes. In children younger than 12 years, the initial dose is 0.05 mg/kg with maintenance doses of 0.02 to 0.05 mg/kg over 10 to 30 minutes. In cases of organophosphate and carbamate poisoning, the atropine dose is 5 to 10 times greater than conventional atropine dosing. Atropine should be continued until the muscarinic symptoms begin to abate. Signs of atropinization include mydriasis, tachycardia, and xerostomia, which help provide parameters for adequate dosing. Atropine should be continued for at least 24 hours after severe exposures and then tapered if symptoms are improving.

13. Which statement regarding the use of pralidoxime in organophosphate and carbamate poisoning is correct?
   A. Atropine should not be used in association with pralidoxime in organophosphate poisoning.
   B. Pralidoxime is not used in carbamate poisoning.
   C. Pralidoxime reverses both muscarinic and nicotinic effects of organophosphate poisoning.
   D. Pralidoxime is a cholinesterase inhibitor.
   Preferred response: B

Rationale

Pralidoxime chloride, the only cholinesterase reactivator in the United States, is an antidote for only the nicotinic symptoms of organophosphate poisonings; therefore, atropine must be used concomitantly. Pralidoxime chloride does not help in carbamate exposures. The dosing for patients older than 12 years is 0.5 to 1.0 g of pralidoxime. Pralidoxime should be given intravenously over 15 to 30 minutes. If needed, the dose may be repeated every 10 to 12 hours, beginning 1 to 2 hours after the initial dose.

Chapter 72: Renal Structure and Function

1. A newborn infant has a patent ductus arteriosus and is placed on ibuprofen to facilitate closure of the heart defect. What is the most obvious sign of the effect on renal perfusion?

   A. Reduction of afferent arterial flow

   B. Reduction in efferent arterial flow

   C. Reduction in medullary blood flow

   D. Reduction in arcuate venous flow

   Preferred response: A

Rationale

Ibuprofen is a nonsteroidal antiinflammatory drug (NSAID) than inhibits prostaglandin production. Prostaglandins play an important role in maintaining afferent arterial vasodilation with the intent of maintaining the glomerular filtration rate. Inhibition of prostaglandin production reduces afferent arterial flow. As a result, blood is shunted around the cortex to the medulla and into the venous system of the kidney, hence C and D are incorrect. Efferent arterial flow may be reduced somewhat in the context of NSAID use, but the effect is predominantly observed at the afferent arterial system, hence A is the correct response.

2. In the early recovery phase of tubular interstitial injury, which of the following would most likely be observed?
   A. Furosemide would be expected to not change tubular flow, and urine output would decrease.
   B. Furosemide would be expected to increase tubular flow, and urine output would decrease.
   C. Furosemide would be expected to increase tubular flow, and urine output would not change.
   D. Furosemide would be expected to not change tubular flow, and urine output would not change.

   Preferred response: D

Rationale

In the setting of early recovery of tubular interstitial injury, the ability to establish medullary gradients is impaired because the polarization of tubular epithelial cells is perturbed. Clinically, this is evident by the polyuric phase of recovery after such injuries happen. Furosemide is a loop diuretic that blocks the NKCC2 channel, which is a significant means of establishing medullary gradients. As such, the efficacy of furosemide in the setting of recovering tubular injury is reduced or absent. Administering furosemide in this setting will have either little or no impact on increasing tubular flow and little or no impact on increasing urine output, which, as noted, may already be in a polyuric state. The correct response is therefore D, as tubular flow and urine output would be expected to either not appreciably change or similarly increase.

3. What directly leads to the arterial blood supply to the tubule in an individual nephron?
   A. The arcuate artery
   B. The efferent arteriole
   C. The interlobar arteriole
   D. The afferent arteriole

   Preferred response: B

Rationale

The blood supply to the tubule directly arises from the efferent arteriole. The arcuate artery feeds the interlobular arteries. The renal artery feeds the interlobar arteries. There is no structure named the interlobar arteriole. The afferent arteriole feeds the glomerulus and efferent arteriole.

4. Which of the following explains the polyuric phase of acute tubular injury?
   A. Excessive transport of water into the interstitium by the tubular epithelium
   B. Excessive transport of water into the urinary space by the tubular epithelium
   C. Deficient transport of water into the urinary space by the tubular epithelium
   D. Deficient transport of sodium into the interstitium by the tubular epithelium

   Preferred response: D

Rationale

Deficient transport of sodium into the interstitium prevents the establishment of a medullary gradient, which is necessary to draw water out of the tubular lumen in the presence of aquaporin channels. Such patients thus have concentrating defects and are polyuric. Response A would result in more water leaving the tubular lumen and decreased urine volume. Regarding response B, water is not transported into the tubular lumen by tubular epithelium but largely arises through filtration in the glomerulus. Although it is true that the urinary space has extra sodium, the sodium arises because of a failure to transport it into the interstitium, not because sodium is actively secreted into the tubular lumen. Deficient transport into the urinary space would, in theory, result in lower urinary volume.

Chapter 73: Fluid and Electrolyte Issues in Pediatric Critical Illness

---

1. An obtunded infant is brought to the PICU from the emergency department just as blood test results are reported as follows: sodium, 116 mEq/L; potassium, 5.9 mEq/L; chloride, 84 mEq/L; bicarbonate, 22 mEq/L; and glucose, 80 mg/dL. After attaching monitor leads, the nurse notices the baby exhibiting right-sided tonic-clonic jerking movements, which rapidly become generalized. The most appropriate immediate therapy is oxygen plus which of the following?

   A. Administer a bolus of phenobarbital intravenously, 10 mL/kg over 5 minutes.

   B. Administer 3% sodium chloride solution intravenously, 5 mL/kg over 15 to 30 minutes.

   C. Administer 25% dextrose intravenously, 2 mL/kg.

   D. Administer a neuromuscular blocker and perform endotracheal intubation.

   Preferred response: B

Rationale

This infant has acute hyponatremic cerebral edema and requires a small increase in plasma osmolality to decrease cerebral irritation and seizure activity. A slow correction of serum sodium should then follow.

2. A neurologically normal 8-month-old, totally breast-fed infant is brought to the PICU with normal blood pressure but is tachypneic with mildly increased work of breathing. His wrists are flared, and costochondral junctions are palpable as distinct nodules. He has hepatomegaly and cardiomegaly. What is the rare but most likely cause of this child's congestive heart failure?

   A. Carnitine deficiency

   B. Inborn error of metabolism

   C. Increased peripheral vascular resistance

   D. Rachitic hypocalcemic cardiomyopathy

   Preferred response: D

Rationale

Prolonged hypocalcemia due to vitamin D deficiency is a rare but recoverable cause of cardiomyopathy. Bony changes as described are characteristic of vitamin D deficiency rickets.

3. Severely hyponatremic patients are at immediate risk because of which of the following?

   A. Inadequate cerebral blood flow

   B. Diabetes insipidus

   C. Diffuse, central nervous system intracellular acidosis

   D. Low extracellular fluid (ECF) osmolality

   Preferred response: D

Rationale

If ECF osmolality falls significantly below intracellular osmolality, the movement of ECF water into cells is favored. The resulting cerebral edema threatens neuronal function and intracranial blood flow and may cause cerebral herniation and death.

4. Hyperphosphatemia causes physiologic disturbance mostly because of which of the following conditions?

   A. Acute renal failure

   B. Hypocalcemia

   C. Impaired unloading of oxygen from hemoglobin

   D. Inorganic metabolic acidosis

   Preferred response: B

Rationale

Severely elevated blood phosphorus levels cause decreased ionized calcium because of Ca-P binding. This phenomenon reduces the free calcium ion available to participate in transmembrane Ca^{++} events critical to the function of neurons, myocytes, and the myocardium.

5. In a critically ill child, which of the following would be expected to increase ionized calcium (Ca^{++})?

   A. Acidosis

   B. Diffuse capillary leak

   C. IL-6 >1000 pg/mL

   D. Packed red blood cell transfusion

   Preferred response: A

Rationale

Acidosis will decrease binding sites on plasma proteins and hence increase Ca^{++}. Citrate anticoagulant will bind calcium and decrease Ca^{++}. Renal failure will result in abnormal vitamin metabolism, and reclamation of calcium in the filtrate also may be

impaired, both resulting in decreased Ca^{++}. Increased free and bound calcium will be lost into the interstitium in the setting of diffuse capillary leak and may result in decreased Ca^{++}. Systemic inflammatory response (IL-6 >1000 pg/mL) is associated with hypocalcemia, perhaps via decreased parathyroid hormone levels.

Chapter 74: Tests of Kidney Function in Children

1. Which of the following statements regarding serum creatinine (Cr) and glomerular filtration rate (GFR) in the pediatric population is true?
   A. At birth, the healthy newborn's GFR is equivalent to adult levels and serum Cr is low.
   B. Maintenance of a stable creatinine in a pediatric patient with a prolonged ICU course is pathognomonic of preservation of renal function.
   C. Serum creatinine lacks sensitivity to acute and small changes in GFR.
   D. The relationship between GFR and serum Cr is linear in children.
   Preferred response: C

Rationale

Serum creatinine is the most commonly used laboratory study to assess renal function in clinical practice. It is simple, convenient, and practical—requiring a single blood sample—and therefore well suited for serial examination. However, the relationship between serum creatinine and GFR is complex and is influenced by several factors other than GFR. Therefore, at best, creatinine provides a crude estimate of the GFR. As illustrated in Fig. Q74.1, serum creatinine bears an inverse, nonlinear relationship with GFR and lacks sensitivity to acute and small changes in GFR. Notably, at low levels of serum creatinine corresponding to normal renal function, a substantial decrease in GFR may occur before being reflected by even a small increase in serum creatinine. In contrast, at higher levels of serum creatinine associated with renal failure, the same absolute rise in creatinine reflects a much smaller loss of remaining renal function. To a first approximation, every doubling of the serum creatinine represents a 50% decline in remaining GFR.

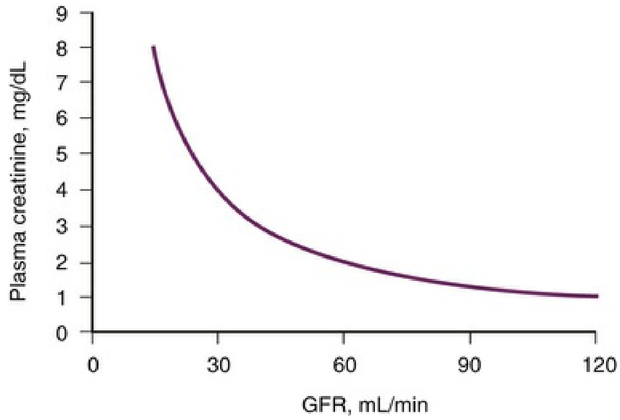

FIG. Q74.1

Creatinine generation is affected by growth in addition to diet and illness, as seen with adults. The reference range for serum creatinine levels representing normal GFR will thus vary with age, size, and gender after puberty. The relationship between GFR and serum creatinine is therefore particularly complex in children. Maturational changes in serum creatinine and GFR do not parallel one another. GFR is physiologically low at birth, whereas serum creatinine is elevated; however, because of fetal-maternal-placental equilibration of creatinine, the elevated creatinine is not indicative of the infant's renal function but rather the mother's. Following birth, GFR steadily increases, reaching adult levels over the next 2 years. Serum creatinine, on the other hand, declines over the first few weeks, becoming reflective of the infant's renal function. The creatinine level then remains stable until approximately 2 years of age as muscle mass accrues proportionally to the increase in GFR. Beyond 2 years of age, when GFR per BSA has fully matured, the ongoing accretion of muscle results in a progressive rise in serum creatinine until adolescence, when adult levels are achieved (0.7 mg/dL for adolescent females and 0.9 mg/dL for adolescent males). Superimposition of a severe or chronic illness associated with malnutrition and muscle wasting makes the interpretation of GFR from serum creatinine alone even more difficult in the pediatric patient. For example, at first glance, maintenance of a stable creatinine in a patient with a prolonged ICU course may be reassuring for preservation of renal function; however, if significant muscle atrophy has occurred, this actually suggests deterioration of renal function. In the steady state when height is used as a surrogate for growth, there is a strong correlation of the parameter Ht/S_{Cr} and GFR.

2. Which of the following factors may be responsible for a decrease in serum creatinine levels?

   A. Anorexia

   B. Muscular body habitus

   C. Use of antibiotics

   D. Use of cimetidine

   Preferred response: A

Rationale

Although the majority of serum creatinine is eliminated by glomerular filtration, a

small but unpredictable amount is eliminated by tubular secretion and gastrointestinal degradation. Proximal tubular secretion of creatinine typically accounts for approximately 10% of its elimination, although considerable inter- and intraindividual variability exists. At normal levels of glomerular filtration rate (GFR), the impact of tubular secretion on GFR is minimal. However, with deteriorating renal function, the proportion of secreted versus filtered creatinine increases, resulting in a lower serum creatinine than predicted for the true level of GFR, thus decreasing the sensitivity for serum creatinine to detect mild decreases in renal function. A similar phenomenon occurs in the setting of moderate-to-severe renal failure, when the bacterial degradation of creatinine within the gastrointestinal tract can become clinically significant, leading to a decrease in serum creatinine concentration. Failure to recognize the influence of tubular secretion and gastrointestinal elimination on serum creatinine values can overestimate renal function and may lead to higher, inappropriate dosing of medications. Conversely, in patients with advanced kidney failure, administration of medications (eg, cimetidine, trimethoprim) that inhibit the tubular secretion of creatinine or administration of antibiotics that mitigate the gastrointestinal degradation of creatinine may elevate serum creatinine and lead to the subsequent underestimation of GFR without any true change in renal function. If not appreciated, this may be misconstrued as worsening renal function and lead to potential underdosing of medications.

Proper interpretation of the serum creatinine as a measure of GFR requires the physician to be knowledgeable about the clinical variables, physiologic processes, and analytic factors that can affect creatinine levels (Table Q74.2). Although the clinical laboratory provides normative reference ranges alongside the results, clinicians should confirm that the reported references are age appropriate and also realize that if the patient has decreased muscle mass (eg, spina bifida, anorexia), even these age-appropriate reference ranges will be incorrect.

3. A 4-year-old girl with sickle cell anemia (weight 15 kg, height 100 cm) is admitted to the PICU with pneumococcal sepsis. Her serum creatinine on admission is 0.4 mg/dL and rises to 1.5 mg/dL 2 days later. What is her estimated glomerular filtration rate (GFR) at this time?

A. 50 to 100 mL/min/1.73 m^2

B. 10 to 50 mL/min/1.73 m^2

C. <10 mL/min/1.73 m^2

D. Unable to determine at this time

TABLE Q74.2

Non-GFR Factors Affecting Creatinine Levels in Children

Factor	SERUM CREATININE LEVEL	
	Increase	**Decrease**
Affecting creatinine generation	Age (infancy through adolescence) Male gender (after puberty) Body habitus (muscular) Diet Consumption of cooked meat Creatine supplements	Chronic illness Anorexia, malnutrition Neuromuscular disease (spina bifida, muscular dystrophy) Liver disease Body habitus (amputation) Diet (vegetarian)

Affecting creatinine elimination	Impaired tubular secretion (trimethoprim, cimetidine)	Tubular secretion
	Impaired extrarenal elimination (sterilization of gastrointestinal flora by antibiotics)	Extrarenal elimination (gastrointestinal degradation)

Preferred response: D

Rationale

Serum creatinine- and creatinine-based equations can only be used to assess GFR when a steady state exists. In the setting of acute kidney injury, an abrupt decline in GFR is associated with a gradual rise in serum creatinine until a new steady state is achieved. During this time period, it is impossible to determine what the true renal function is. Use of the serum creatinine to estimate GFR in this period will result in an overestimation of the renal function. A doubling of serum creatinine corresponds to an approximate 50% decrease in remaining renal function. Therefore, the patient's nearly fourfold increase in serum creatinine suggests that her GFR is less than 25% of normal. Serum creatinine should be monitored once or twice a day to better estimate GFR.

4. A 16-year-old adolescent presents to the ER following an acetaminophen overdose 2 days ago. She has had persistent nausea and vomiting since then. She does not recall when she last urinated. On arrival in the ER, her vital signs are heart rate, 80 beats per minute, and blood pressure, 124/68 mm Hg. Blood tests on admission were notable for sodium (Na) of 138 mmol/L and creatinine (Cr) of 1.38 mg/dL. Urine studies showed a specific gravity of 1.035, 2+ protein, negative blood; urine Na was 30 mmol/L and urine Cr was 80 mg/dL. Which statement is correct?

A. Fractional excretion of Na (FENa) is 0.04%, consistent with a prerenal state.

B. FENa is 0.4%, consistent with a prerenal state.

C. FENa is 4%, consistent with acute tubular necrosis.

D. Urine sodium (UNa) is >20 mmol/L, consistent with acute tubular necrosis.

Preferred response: B

Rationale

The fractional excretion of Na (FENa) is calculated using the formula:

$$FENa = (UNa/SNa)/(UCr/SCr) \times 100$$

For this patient, the FENa = (30/138)/(80/1.38) × 100 = 0.4%.

A fractional excretion of Na less than 1% in an oliguric patient suggests a prerenal state. The urine sodium is also typically less than 20 mmol/L in prerenal states as the kidney avidly tries to reclaim sodium and water; however, the urine sodium can exceed 20 mmol/L in some cases as the final concentration of sodium in the urine will depend not only on the amount of sodium reclaimed by the tubules but also on the amount of water reabsorbed in the distal tubule under the influence of antidiuretic hormone. FENa accounts for this differential degree of water reabsorption and therefore provides a more accurate reflection of the kidney's ability to conserve sodium than the urine sodium concentration alone. A high urine-specific gravity would be more consistent with a prerenal state than acute tubular necrosis.

Chapter 75: Glomerulotubular Dysfunction and Acute Kidney Injury

1. During states of reduced cardiac output and intravascular volume depletion, which substances help preserve renal vascular perfusion?

   A. Angiotensin II

   B. Kallikrein

   C. Prostaglandin I2

   D. Vasopressin

   Preferred response: C

Rationale

Vasopressin acts indirectly to increase vascular volume by stimulating salt and water reabsorption. Angiotensin II overall contributes to reduced renal blood flow, but it will also cause efferent arterioles to vasoconstrict to improve filtration fraction at the expense of blood flow. Prostaglandin I2 released locally will cause afferent arteriolar vasodilation and counteract the vasoconstrictive effects of the systemic angiotensin II.

2. Which of the following statements regarding the response of the kidney to reduced renal blood flow is true?

   A. Outer cortical blood flow is preferentially reduced.

   B. The renal medulla is spared from ischemic injury because it maintains a higher partial pressure of oxygen.

   C. The proximal tubule is the least affected region of the nephron.

   D. Tubular cell necrosis and resultant luminal obstruction of flow results in vasodilation of the afferent arteriole via tubuloglomerular feedback.

   Preferred response: A

Rationale

Although cortical blood flow is reduced preferentially, the medulla is not spared from hypoperfusion and hypoxia-induced injury as it has a low partial pressure of oxygen. The proximal tubule is the most affected region of the nephron. In response to tubular obstruction of flow, the luminal concentration of sodium increases and feeds back to vasoconstrict the afferent arteriole.

3. Which of the following distinguishes typical and atypical hemolytic uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP)?

   A. Atypical HUS is the only one of these diseases that results from activation of the alternative complement pathway.

B. Neurologic disease only occurs in TTP.

C. The treatment of TTP but not HUS relies on platelet transfusion.

D. TTP involves a deficiency or antibody-mediated inactivation of ADAMTS13.

Preferred response: D

Rationale

Neurologic and other extrarenal manifestations can occur in all three forms of the thrombotic microangiopathies. Activation of the alternative complement pathway may be the underlying pathologic mechanism in all three diseases. None of the diseases should be treated with platelet transfusion routinely, as the thrombotic microangiopathy may worsen.

4. An African-American child is being treated for Burkitt lymphoma with rasburicase in an effort to reduce the risk of acute kidney injury secondary to tumor lysis syndrome. Metabolic acidosis with rising lactate develops acutely. Which of the following would explain the pathophysiology involved in this scenario?

A. Impaired renal ammonium synthesis

B. Methemoglobinemia

C. Pulmonary hypertension with right-to-left intracardiac shunt

D. Renal bicarbonate wasting

Preferred response: B

Rationale

Recombinant urate oxidase (rasburicase) exerts its pharmacologic activity by enzymatic oxidation of uric acid into allantoin. It works rapidly, often dropping the uric acid to less-than-normal levels within hours. Although contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency, overall it is well tolerated. The traditional recommended dosage is 0.15 to 0.20 mg/kg administered intravenously daily for up to 7 days. Investigators recommend the use of rasburicase as the first-line intervention for high-risk patients and as backup moderate-risk therapy for patients in whom hyperuricemia develops despite the use of allopurinol and hydration. Rasburicase is remarkably well tolerated. The rare but serious adverse events that require prompt and permanent discontinuation of rasburicase are methemoglobinemia and hemolysis.

Chapter 76: Acid-Base Balance and Disorders

1. Which of the following physiologic buffering systems includes both volatile and nonvolatile forms of the parent acid?

A. Carbonic acid/bicarbonate

B. Citric acid/citrate

C. Dihydrogen phosphate/monohydrogen phosphate

D. Lactic acid/lactate

E. Uric acid/urate

Preferred response: A

Rationale

Citric acid, phosphoric acids, lactic acid, and uric acid have no volatile forms. However, the bicarbonate/carbonic acid system has the tremendous advantage of its interconversion with CO_2, the volatile form of H_2CO_3, which means this is an "open system" buffer:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-$$

Any increase in $[H^+]$ (or drop in pH) will shift the above reaction to the left, including an increase in alveolar ventilation to eliminate the resultant increase in CO_2. This respiratory response begins within minutes. This respiratory response is particularly useful to the tissues, because of its rapid effect on intracellular pH as well as extracellular pH. Carbon dioxide crosses cell membranes easily, so changes in PCO_2 affect intracellular pH rapidly and in a predictable direction.

2. Cardiopulmonary arrest results in metabolic and respiratory acidosis. In addition to the carbonic acid/bicarbonate buffering system, which of the following represents the body's first, abundant, and immediate line of defense against any alteration of pH of the body fluids?

   A. Ammonium

   B. Citrate

   C. Dihydrogen phosphate

   D. Proteins

   E. Urate

   Preferred response: D

Rationale

Together, extracellular and intracellular buffers provide a volume of distribution close to that of the total body water to any exogenous acid load (or deficit). This represents a formidable capacity for resisting changes in pH.

3. Which of the following ions can exist in both charged and altered charged forms and hence is considered a weak ion?

   A. Ca^{++}

   B. Cl^-

   C. $H_2PO_4^-$

   D. K^+

   E. Mg^{++}

   Preferred response: C

Rationale

Some ions are fully dissociated in aqueous solutions and are called *strong ions;* these include Na^+, K^+, Ca^{2+}, Mg^{2+}, and Cl^-. Others, such as albumin, phosphate, and HCO_3-, can exist as both charged (ie, dissociated) and uncharged forms and are called *weak ions.* Certain organic acids, such as lactate and others, are nearly completely dissociated under physiologic conditions, and so they are considered strong ions. Weak anions, but not strong anions, can participate in buffering systems.

4. Apparent strong ion difference is typically calculated as follows:

$$SID_{APP} = ([Na^+]+[K^+]+[Ca^{2+}]+[Mg^{2+}])-([Cl^-])$$

For critically ill patients, which of the following should also be included in the strong anion group if elevated?

A. Albumin

B. Carbon dioxide ($PaCO_2$)

C. Bicarbonate

D. Lactate

E. Phosphate

Preferred response: D

Rationale

Certain organic acids, such as lactate, are nearly completely dissociated under physiologic conditions, and so they are considered strong ions. Carbon dioxide does not contribute anything to the ion difference. Albumin, bicarbonate, and phosphate are all weak anions and play no role in the strong ion difference.

5. During normal lactate production derived from skeletal muscle, gut, brain, and circulating erythrocytes (~1 mmol/kg/hour), which of the following immediately involves lactate in gluconeogenesis?

A. Catabolism to urea

B. Cori cycle

C. Oxidation to acetyl-CoA

D. Oxidation to pyruvate

E. Transamination to oxaloacetate

Preferred response: B

Rationale

The healthy liver uptakes most (circulating) lactate and recycles it through three primary options: conversion back to glucose (gluconeogenesis; Cori cycle); oxidation back to pyruvate, which subsequently can be oxidized to CO_2 via the Krebs cycle; or transamination into alanine.

6. A toddler with septic shock is initiated on an infusion of epinephrine, and serum lactate is noted to increase from 2.5 to 3.5 mmol/L at a time when the blood pressure is 110/40 and qualitative cardiac function by ultrasonography is hyperdynamic. Which of the following is the most likely cause of this observation?

   A. Aerobic glycolysis

   B. Cellular lysis

   C. Oxygen debt

   D. Mitochondrial dysoxia

   E. Tissue hypoxia

   Preferred response: A

Rationale

Evidence now supports the view that sepsis-associated hyperlactatemia is not due only to tissue hypoxia or anaerobic glycolysis and that this response may actually facilitate bioenergetic efficiency through an increase in lactate oxidation. In this sense, the characteristics of lactate production best fit the notion of an adaptive survival response that increases in intensity as disease severity increases. Skeletal muscle appears to be a leading source of lactate formation as a result of exaggerated aerobic glycolysis through Na^+K^+ATPase stimulation by circulating epinephrine, both endogenous and exogenous. Increased lactate as a result of hypoxia or dysoxia may be more the exception than the rule, at least in the hyperdynamic, hypermetabolic phase of sepsis.

7. Two days following admission for new onset diabetes mellitus, diabetic ketoacidosis, and clinically suspected cerebral edema, a 3-year-old is being transitioned to subcutaneous insulin but is found to have a persistent metabolic acidosis, despite normalization of blood glucose for approximately 12 hours. What is the most likely cause of the metabolic acidosis?

   A. β-hydroxybutyrate

   B. Gastric acid production

   C. Hyperchloremia

   D. Lactic acid

   E. Metformin toxicity

   Preferred response: B

Rationale

Because of concern for cerebral edema, this child was likely administered normal saline for replacement and maintenance fluid. Because sodium and chloride are both strong ions, IV administration of 0.9% NaCl necessarily will decrease plasma strong ion difference, creating a strong ion acidosis, as long as such an infusion does not cause a change in PCO_2 or albumin or phosphate concentrations. Lactate and β-hydroxybutyrate should be normal in this patient. It is not likely that metformin was utilized in the treatment plan for DKA. Increased gastric acid production is not a cause of systemic metabolic acidosis.

Chapter 77: Renal Pharmacology

1. Which of the following diuretic categories is considered the most effective in producing diuresis?
   A. Carbonic anhydrase inhibitors
   B. Loop diuretics
   C. Potassium-sparing diuretics
   D. Thiazide diuretics
   Preferred response: B

Rationale

Loop diuretics (eg, furosemide, bumetanide, torsemide) are antagonists of the Na^+/K^+2Cl^- cotransported in the ascending loop of Henle. Inhibition of the transporter increases the sodium, and thus water, content of the filtrate and also diminishes the medullary osmotic potential. Both of these increase the excretion of sodium and water.

2. A 16-year-old girl who received a deceased donor renal transplant develops delayed graft function and has an estimated glomerular filtration rate (GFR) of 35 mL/min/1.73m^2. In addition to her immunosuppressive medications, she is prescribed ganciclovir for cytomegalovirus (CMV) prophylaxis. Which of the following factors is most important in determining the correct ganciclovir dosage?
   A. The donor CMV status
   B. The extent of her fluid overload
   C. The extent of her reduced kidney function
   D. The need for diuretics
   Preferred response: C

Rationale

The elimination of ganciclovir from the body is directly related to kidney function, as ganciclovir is predominantly eliminated by glomerular filtration. Failure to adjust the dose in the presence of decreased kidney function will lead to an accumulation of ganciclovir and possible toxicity. Although fluid overload and her albumin concentration may impact the volume of distribution, it is unlikely to impact a dosage adjustment. The donor CMV status and need for concurrent diuretics will not impact ganciclovir dosing.

Chapter 78: Pediatric Renal Replacement Therapy in the Intensive Care Unit

1. A 9-year-old male began hemodialysis for acute kidney injury due to multiorgan failure from septicemia. He has tolerated his sessions well but developed significant thrombocytopenia, and concern for heparin-induced thrombocytopenia was raised. Which of the following methods is most likely to assure effective hemodialysis sessions and also address the concern for heparin-induced thrombocytopenia?

   A. Change unfractionated heparin to low-molecular-weight heparin.

   B. Eliminate heparin and use citrate-containing dialysate.

   C. Give a heparin bolus at the start of hemodialysis but avoid the use of continuous infusion.

   D. Use half the previous dose of unfractionated heparin.

   Preferred response: B

Rationale

Heparin-induced thrombocytopenia is a well known but rare complication in patients exposed to heparin. Patients on hemodialysis are at risk for forming clots when their blood is exposed to the extracorporeal circuit. Although heparin is the most common anticoagulant prescribed during hemodialysis, any method of anticoagulation can be utilized. Citrate functions as an anticoagulant due to its ability to chelate calcium, which is an essential cofactor in the clotting cascade and for platelet activation. Citrate can be administered as an infusion, or citrate-containing dialysate may be used. The first is used mostly in continuous renal replacement therapy (CRRT). Dialysate solutions that have substituted some of the acetate in the acid bath with citrate have been found to function well as an anticoagulant. The citrate in the dialysate will bind calcium locally at the dialyzer membrane, preventing clotting within the dialyzer. Monitoring of ionized calcium is not required as the concentration of citrate is low, and thus the patient is not at risk for hypocalcemia. The risk for heparin-induced thrombocytopenia (HIT) is not dose dependent, thus reducing the dose will not be beneficial. Use of low-molecular-weight heparin (LMWH) is not a good choice, as risk of HIT, though lower, is still a possibility; therefore for patients found to have HIT from unfractionated heparin, LMWH is contraindicated. Changing modality will not mitigate the risk of HIT due to heparin exposure.

2. A 5-year-old male has Shiga toxin–mediated hemolytic uremic syndrome. He is anuric with significant electrolyte abnormalities refractory to medical management; he will likely require renal replacement therapy for the next 1 to 2 weeks. Of the following, which anatomic location would be the preferred option for placement of a hemodialysis catheter?

   A. Femoral vein

   B. Left internal jugular vein

   C. Right internal jugular vein

   D. Subclavian vein

   Preferred response: C

Rationale

The most desirable site for a double lumen hemodialysis catheter is the right internal jugular vein; it provides access to a high-flow area in the superior vena cava/right atrium, permits a straight venous path for the operator from insertion site to the target location, can be readily accessed for insertion of either tunneled or nontunneled catheters depending on the indication, allows ambulation and reduces discomfort for the patient as compared to the femoral site, and is less susceptible to complicating venous stenosis that will limit future permanent vascular access creation such as AV fistula. By contrast, subclavian access is associated with increased risk of stenosis that would result in loss of potential sites for AV-fistula formation in the ipsilateral arm, and therefore it is not recommended. A femoral vein is associated with an increased risk of infection and limits ambulation. A saphenous vein is too small to support a double lumen venous hemodialysis catheter. A left internal jugular vein is more challenging for successful placement of the catheter.

3. Of the following clinical scenarios, which would be better served by a renal replacement therapy other than continuous renal replacement therapy (CRRT)?
   A. A 5-month-old female with complications following heart transplant, on ECMO
   B. A 12-year-old male with meningococcemia, hypotension, on multiple vasoactive drugs, with oliguria and serum creatinine 2.8 mg/dL
   C. A 14-year-old female with sepsis and multiorgan dysfunction, including renal failure, following orthotopic liver transplant
   D. A 17-year-old male with acute methanol intoxication
   Preferred response: D

Rationale

CRRT is a reasonable choice for nearly any critically ill patient who requires renal replacement therapy. CRRT is appropriate for patients with volume overload or renal dysfunction in the setting of hypotension or multisystem organ failure to provide continuous renal support for fluid and metabolic balance. CRRT machines can be connected directly to an ECMO circuit. Acute intoxications call for rapid removal of the toxic molecule; for this reason, a more efficient modality such as intermittent hemodialysis would be more appropriate.

Chapter 79: Acute Severe Hypertension

---

1. A 16-year-old boy is transported to the PICU from an outlying hospital where he had presented with status epilepticus and severe hypertension, with blood pressure (BP) readings ranging from 175–200/110–120 mm Hg. His seizures were controlled with lorazepam prior to transport, but his BPs remain elevated upon admission to the PICU. No family members are yet available to provide history. His examination is notable for marked periorbital edema and rales at the lung bases bilaterally. Laboratory studies from the outside hospital reveal hematuria, proteinuria, and an elevated serum creatinine of 2.1 mg/dL. Which of the following antihypertensive agents would be most appropriate to administer in this

setting?

A. Intravenous enalaprilat

B. Intravenous furosemide

C. Intravenous nicardipine

D. Intravenous sodium nitroprusside

Preferred response: C

Rationale

The child has a hypertensive emergency, and immediate BP reduction with an intravenous agent is indicated. Glomerulonephritis is the likely cause of his acute severe hypertension as evidenced by the peripheral edema, pulmonary edema, and laboratory findings. Given the renal dysfunction, enalaprilat and nitroprusside would be contraindicated. Furosemide might eventually be administered to address volume overload, but it would not be appropriate as the first agent. Thus nicardipine is the best agent of the available choices.

2. A 3-year-old girl is admitted to the PICU from the emergency department, where her parents had brought her for evaluation of headache and persistent vomiting. Vital signs in the ED were notable for a heart rate of 140 beats per minute and blood pressure (BP) readings of 135–142/87–92 mm Hg; BP measurements were similar in the upper and lower extremities. She had a protuberant abdomen on physical examination that was diffusely tender to palpation without rebound tenderness. There was a right upper quadrant mass immediately below the costal margin that on ultrasound had a complex appearance and seemed to be displacing the right kidney laterally. Serum chemistries were normal, but a complete blood cell count (CBC) was remarkable for hemoglobin of 8.5 g/dL. Oral isradipine had been administered in the ED but she vomited shortly after the dose. BP on admission to the PICU is 144/90 mm Hg. What is the best next step in her management?

A. Give an intravenous bolus dose of labetalol and begin a labetalol infusion; obtain Dinamap BPs every 1 to 2 minutes.

B. Insert an arterial line and begin a nicardipine infusion.

C. Place a nasogastric tube and repeat a dose of isradipine; obtain Dinamap BPs every 1 to 2 minutes.

D. Place a nasogastric tube and administer a dose of propranolol; obtain Dinamap BPs every 1 to 2 minutes.

Preferred response: A

Rationale

The child is exhibiting signs of hypertensive urgency as manifested by the headache and vomiting. She is at risk of progressing to more severe neurologic manifestations of her severe hypertension and requires prompt BP reduction to prevent this from occurring. The cause of her severe hypertension is likely a neuroblastoma, which causes severe hypertension by producing catecholamines; increased renin secretion due to the renal displacement may also be playing a role. Oral medications should

not be given because of the persistent vomiting and because the magnitude of BP reduction is unpredictable. Labetalol provides a blockade of α and β receptors and is a better choice of agent than nicardipine in this case; however, if labetalol were unavailable, nicardipine would be an acceptable choice. A bolus dose of labetalol will reduce the BP promptly, allowing time for the pharmacy to prepare an infusion. Dinamap monitoring of BP is acceptable until such time as an arterial line can be placed.

3. A 5-year-old child with a blood pressure of 180/110 mm Hg is admitted to the pediatric intensive care unit for initiation of blood pressure management. Which of the following statements summarizes a reasonable approach to therapy for this patient?
   A. Children who experience a hypertensive emergency should be evaluated for an antecedent cause for their hypertension.
   B. Nitroprusside should be avoided as a first-line agent because of the risk of cyanide toxicity in this setting.
   C. Particularly for hydralazine, genetic variation affecting drug metabolism is unlikely to be clinically important.
   D. Unlike the case with adults, angiotensin-converting enzyme inhibitors (eg, enalaprilat) may be escalated quickly in children with high renin hypertension.
   Preferred response: A

Rationale

Children who experience a hypertensive crisis typically have histories of long-standing hypertension. Although a child can present with a hypertensive crisis and no antecedent history, this situation is not common. Sodium nitroprusside remains a first-line therapy for hypertensive emergencies, largely because of its long history of use, rapid onset, and short half-life that facilitates titration to achieve controlled blood pressure reduction. Unfortunately, its safety profile is poor because of its toxic metabolites, such as cyanide and thiocyanate, which can accumulate quickly in persons with conditions commonly associated with hypertension, such as renal insufficiency and failure. Clinical studies have demonstrated that hypertensive patients with high renin levels are exquisitely sensitive to angiotensin-converting enzyme inhibitors, which can cause a rapid decline in blood pressure, and thus care must be taken in using them in this population. Hydralazine metabolism via acetylation is genetically determined.

4. A teenager with a newly diagnosed pheochromocytoma exhibits a blood pressure of 170/110 mm Hg with a heart rate of 100 beats per minute and cool distal extremities beyond the elbows and knees. Which of the following medications is contraindicated as a first-line agent for the patient's hypertension?
   A. Esmolol
   B. Hydralazine
   C. Labetalol
   D. Nicardipine
   Preferred response: A

Rationale

The use of pure β-blockers should be avoided in children with suspected catecholamine-secreting tumors because the stimulation of α receptors from pheochromocytoma catecholamines without opposing stimulation of vascular β-adrenergic receptors can severely worsen blood pressure. In addition, if β-adrenergic blockade is undertaken before α-adrenergic blockade in such patients and α-blockade is excessive leading to marked vasodilation, the ability to maintain cardiac output by increasing heart rate and cardiac contractility will be impaired.

5. A child is admitted from the solid organ transplantation ward to the pediatric intensive care unit with severe hypertension associated with changes in mental status. Which of the following statements correctly summarizes the likely clinical scenario?
   A. Common symptoms of posterior reversible encephalopathy syndrome (PRES) include seizures, altered mental status, headaches, and visual changes.
   B. Magnetic resonance imaging findings associated with PRES include edema of the gray matter in a parietooccipital distribution.
   C. PRES is typically associated with corticosteroid prescription for immunosuppression.
   D. Radiographic findings resolve more quickly than clinical symptoms associated with PRES after blood pressure is controlled.
   Preferred response: A

Rationale

PRES is characterized by the sudden onset of hypertension, headaches, altered mental status, seizures, visual loss, and even cortical blindness. Neuroimaging studies during PRES typically demonstrate cerebral edema that affects the white matter in a parietooccipital distribution and is associated with immunosuppressive therapy (especially cyclosporine and tacrolimus), acute glomerulonephritis, eclampsia of pregnancy, and hypertensive encephalopathy. Typically, clinical signs associated with PRES improve before radiographic findings are resolved.

Chapter 80: Cellular Respiration

---

1. What is the best general overview of cellular respiration?
   A. Glycolysis, β-oxidation, and amino acid catabolism are metabolic pathways within the mitochondria.
   B. Glycolysis, β-oxidation, and amino acid catabolism provide sufficient ATP to support cellular activities and overall organ function.
   C. Glycolysis, β-oxidation, and amino acid catabolism produce carnitine, which is used by the Krebs cycle to produced electron-rich NADH and $FADH_2$, which then feed the mitochondrial electron transport system to produce ATP and reduce oxygen to water.
   D. Glycolysis, β-oxidation, and amino acid catabolism produce acetyl-CoA, which

is used by the Krebs cycle to produced electron-rich NADH and $FADH_2$, which then feed the mitochondrial electron transport system to produce ATP and reduce oxygen to water.

Preferred response: D

Rationale

Cellular respiration consists of a series of three related biochemical reactions:

(1) Glycolysis of carbohydrates, β-oxidation of fatty acids, and catabolism of amino acids in the cytosol to produce acetyl-coenzyme A (acetyl-CoA).

(2) Metabolism of acetyl-CoA in the mitochondrial Krebs cycle to produce electron-rich nicotinamide dinucleotide (NADH) and flavin adenine dinucleotide ($FADH_2$)

(3) Shuttling of electrons from NADH and $FADH_2$ to oxygen through the mitochondrial electron transport system in order to synthesize ATP through oxidative phosphorylation

2. A 3-year-old boy with a history of acute lymphoblastic leukemia is admitted with fever and lethargy. Vital signs are temperature, 39.3°C; heart rate, 174 beats per minute; respiratory rate, 32 per minute; and blood pressure, 74/30 mm Hg. He has an indwelling central line for chemotherapy. Laboratory blood tests are sent from this central line, and 60 mL/kg of intravenous fluids are administered, as well as broad-spectrum antibiotics. A norepinephrine infusion is also started. Following this initial resuscitation and antipyretics, fever has resolved and the repeat vital signs are heart rate, 130 beats per minute; respiratory rate, 23 per minute; and blood pressure, 93/54 mm Hg. The measured $ScvO_2$ now is 82%. How can you interpret the $ScvO_2$ result?

A. Despite improvement in vital signs, resuscitation is not adequate, and an infusion of dobutamine or milrinone is indicated.

B. $ScvO_2$ should be 70%, so this must represent a laboratory error.

C. The high $ScvO_2$ suggests that global oxygen delivery (DO_2) has been restored to a level that currently exceeds total body oxygen consumption (VO_2) and may signify an altered state of cellular respiration known as cytopathic hypoxia.

D. The nurse accidentally sent an arterial rather than a venous blood sample.

Preferred response: C

Rationale

The venous oxygen saturation sampled from a central vein (preferably at the superior vena cava-right atrial junction) provides a bedside measure of the global balance between oxygen delivery and consumption. Normal $ScvO_2$ values are approximately 65% to 75% when arterial oxygen saturation is 100% because the oxygen extraction ratio (ERO_2) is typically 0.25 to 0.35. A low $ScvO_2$ suggests that total body oxygen consumption exceeds normal oxygen delivery, whereas a high $ScvO_2$ suggests that total body oxygen consumption may be diminished compared to

the normal state of oxygen delivery. The inability of cells to effectively utilize oxygen to generate ATP within mitochondria has been termed *cytopathic hypoxia*. Although the *routine* use of $ScvO_2$ monitoring in septic shock has been called into question, targeted measurement of $ScvO_2$ can provide a bedside measure of the global state of bioenergetic homeostasis.

3. What is the product of a four-electron reduction of molecular oxygen?
   A. Hydrogen peroxide
   B. Hydroxyl radical
   C. Triplet oxygen
   D. Water
   Preferred response: D

Rationale

Complete reduction of oxygen to water by the addition of four electrons characterizes cellular respiration that occurs in the mitochondria. Incomplete oxygen reduction yields reactive oxygen species that may mediate pathophysiology directly or through an alteration of intracellular signaling.

4. What is the ultimate source of electrons for oxygen reduction in the mitochondria?
   A. Energy substrate
   B. Hydride anion
   C. Reduced form of flavin adenine dinucleotide ($FADH_2$)
   D. Reduced nicotinamide adenine dinucleotide (NADH)
   Preferred response: A

Rationale

Carbohydrates, proteins, and lipids (energy substrates) are oxidized with the resultant formation of hydrides in the form of $FADH_2$, NADH, and NADPH. Two electrons derived from each hydride bond represent the reducing equivalents for reduction of oxygen to water.

5. In considering resuscitation of a critically ill patient with shock, what rate-limiting process can the intensivist clinically manipulate that will result in the most efficient adenosine triphosphate production in tissues?
   A. Free fatty acid availability
   B. Glucose availability
   C. Oxygen consumption
   D. Oxygen delivery
   Preferred response: D

Rationale

Delivery of oxygen to tissues facilitates aerobic metabolism that is nearly 20 times more efficient in terms of adenosine triphosphate production than anaerobic

metabolism. Although the intensivist can alter the type of energy substrate available, this intervention has limited impact compared with oxygen availability. Improved oxygen delivery will hasten lactate clearance. Currently, for the most part, the effect of resuscitation on oxygen consumption occurs indirectly through effects on oxygen delivery that intensivists can manipulate directly.

6. A child is being monitored during a prolonged resuscitation for meningococcal septic shock. Both blood pressure and heart rate are nearly age appropriate, and capillary refill is <2 seconds. Pulse oximetry saturation is 98%, whereas a blood sample derived from a right internal jugular catheter with the distal tip at the junction of the superior vena cava and right atrium indicates a hemoglobin of 10.4 and central venous oxygen saturation ($Scv{O_2}$) of 81% at a time when the central venous pressure is 12 mm Hg. Which of the following conditions most accurately describes this physiologic scenario?
   A. Anemic dysoxia
   B. Cytopathic dysoxia
   C. Hypoxic dysoxia
   D. Stagnant dysoxia
   Preferred response: B

Rationale

By all accounts, oxygen delivery appears adequate because oxygen content and cardiac output seem appropriate. The high $Scv{O_2}$ indicates low oxygen consumption.

7. Two days following initiation of resuscitation for a 20% total body surface area scald burn, a toddler remains in the pediatric intensive care unit with a persistent metabolic acidosis. Current vital signs include the following: temperature, 38.5°C; breathing rate, 24; heart rate, 130; and blood pressure, 100/70 mm Hg. Capillary refill is 2 seconds, and urine output is now ~1 mL/kg/hour. Pulse oximetry saturation is 98% on 2 L/min of oxygen delivered by nasal prong. Current laboratory findings include the following: pH, 7.33; $Pa{CO_2}$, 30 mm Hg; $Pa{O_2}$, 90 mm Hg; HCO_3, 15 mmol/L; Na, 143 mEq/L; K, 4.0 mEq/L; Cl, 116 mEq/L; and total carbon dioxide, 15 mEq/L. What is the most likely explanation for the patient's persistent metabolic acidosis?
   A. Impaired lactate clearance
   B. Inadequate central venous preload
   C. Resuscitation with 0.9% saline solution
   D. Unrecognized carbon monoxide poisoning
   Preferred response: C

Rationale

This child appears to exhibit normal clinical hemodynamics. The metabolic acidosis is hyperchloremic and nonanion gap in nature, likely because of large-volume 0.9% saline solution administration. With normal urine output and capillary refill, cardiac output and hence preload are likely adequate. Carbon monoxide poisoning,

ketoacidosis, and lactic acidosis are all associated with an elevated anion gap.

8. For a previously healthy infant with respiratory syncytial virus bronchiolitis and a pulse oximetry saturation of 90%, excluding the increased work of breathing, no change in oxygen extraction, and insignificance of dissolved oxygen, what approximate increase in cardiac output as a percentage, compared with a normal baseline, would be required to maintain oxygen delivery at the baseline status?
   A. 5%
   B. 10%
   C. 15%
   D. 20%
   Preferred response: B

Rationale

Baseline status:

$$\begin{aligned} DO_2 &= CaO_2 \times CO = (Hb \times 1.34 \times \text{saturation}) \times CO \\ &= (Hb \times 1.34 \times 1.0) \times CO \end{aligned}$$

where DO_2 = delivery of oxygen, CaO_2 = arterial oxygen content, CO = cardiac output, and Hb = hemoglobin.

Assuming baseline Hb saturation is 1.0, if saturation decreases by 10%, then CO must increase by 10% for DO_2 to remain constant.

9. Which element of shock resuscitation has the greatest direct effect in terms of increasing oxygen delivery?
   A. Administer fluid bolus.
   B. Administer red blood cell transfusion.
   C. Increase inspired oxygen concentration.
   D. Increase cardiac inotropy.
   Preferred response: D

Rationale

$$Do_2 = [(1.34 \times Hb \times Sao_2) + (0.003 \times Pao_2)] \times CO$$

where Do_2 = delivery of oxygen, Cao_2 = arterial oxygen content, CO = cardiac output, and Hb = hemoglobin.

Increasing Hb will increase Do_2 directly and linearly, whereas increasing cardiac preload, increasing cardiac contractility, and decreasing cardiac afterload affect Do_2 indirectly through an effect on CO. Increasing fraction of inspired oxygen increases Pao_2 and arterial oxygen saturation (Sao_2) indirectly via the Pao_2–Sao_2 curvilinear relationship.

Chapter 81: Biology of the Stress Response

1. Which of the following terms specifically refers to an organism's ability to adapt to or cope with the stresses and strains imposed on it?

   A. Allostasis

   B. Equilibrium

   C. Homeostasis

   D. Resiliency

   Preferred response: D

Rationale

Resiliency is defined as an organism's ability to adapt to or cope with the stresses and strains imposed on it.

2. A child has been treated for 24 hours in a burn center for a 40% total body surface scald burn. Which of the following is most likely to be decreased at this time?

   A. Aldosterone

   B. Cortisol

   C. Epinephrine

   D. Triiodothyronine

   Preferred response: D

Rationale

Aldosterone, cortisol, epinephrine, and vasopressin would all be up-regulated as part of the stress response to ensure circulating volume and energy substrate. On the other hand, conversion of thyroxine to triiodothyronine is likely to be depressed as an aspect of the *sick euthyroid* syndrome, perhaps to conserve energy.

3. A child with meningococcemia exhibits fever, hypotension, hypoxemia, acidosis, and distal extremity necrosis. What element of the stress response integrates these various afferent signals into a coordinated stress response?

   A. Aortic arch receptors

   B. Hypothalamus

   C. Juxtaglomerular apparatus

   D. Zona fasciculata

   Preferred response: B

Rationale

The hypothalamus is responsible for recognizing, initiating, and regulating the stress response. Each of the other anatomic locations participate in the stress response, but

they provide no overall regulation for it: aortic arch receptors—sense vascular stretch and hence hypotension; juxtaglomerular apparatus—initiation site of the renin-angiotensin-aldosterone axis; zona fasciculata—site of cortisol synthesis in the adrenal.

4. Synthesis and release of which of the following hormones might be further impaired by initiation of an infusion of dopamine?

   A. Cortisol

   B. Epinephrine

   C. Glucagon

   D. Prolactin

   Preferred response: D

Rationale

Synthesis and release of prolactin, required for lymphocyte growth and differentiation, is under tonic inhibition by endogenous dopamine. Control of synthesis and release of the other hormone choices do not involve dopamine.

5. Which of the following mitochondrial changes is associated with short-term exposure to stress?

   A. Apoptosis

   B. Biogenesis

   C. Increased reactive oxygen species generation

   D. Structural abnormalities

   Preferred response: B

Rationale

The mitochondria generate energy for the enormous energy demands of the stress response. Early in the stress response this may be facilitated by mitochondrial biogenesis. If the stress response is prolonged or maladaptive, mitochondrial abnormalities have been reported, including respiratory chain dysfunction, increased reactive oxygen species generation, mitochondrial structural abnormalities, apoptosis, and cell death.

Chapter 82: Inborn Errors of Metabolism

1. A 3-day old, previously well, term female infant presents with coma and severe hypertonia. Laboratory evaluation reveals a venous pH of 7.2 and 2+ ketonuria. The most useful specialized diagnostic testing for the specific detection of an inborn error of metabolism (IEM) in this clinical scenario includes which of the following?

   A. Cerebrospinal fluid lactate

B. Plasma amino acid analysis

C. Plasma very-long-chain fatty acid analysis

D. Urine mucopolysaccharide analysis

Preferred response: B

Rationale

According to the classification of IEM given in the text, the age of the patient and the catastrophic clinical presentation would suggest a disorder among the group 3 IEMs with symptoms of intoxication. The relatively mild metabolic acidosis and moderate ketonuria would be most consistent with subgroup A, maple syrup urine disease, but disorders of subgroup B or D cannot be ruled out. Analysis of plasma amino acids and urine organic acids will differentiate among the possible disorders.

2. A term infant presents with coma, seizures, and severe ketoacidosis (pH 6.9) at 40 hours of age. You obtain urine for organic acid analysis and measure blood lactate and ammonia levels. After obtaining blood, urine, and cerebrospinal fluid for culture, you initiate empiric antibiotic therapy. What is the next step in the management of this child?

A. Initiate an insulin infusion

B. Initiate nasogastric feedings with cow's milk–based formula

C. Initiate total parenteral nutrition

D. Initiate a 3% NaCl infusion

Preferred response: C

Rationale

This clinical presentation could be consistent with a number of different IEMs, but regardless of the specific disorder affecting this infant, administration of a cow's milk–based formula would likely exacerbate the acidosis by continuing to supply the toxic substrate. Enteral nutrition should be discontinued and replaced by parenteral administration of dextrose until the diagnosis can be clarified and a specific dietary therapy can be designed.

Chapter 83: Genetic Variation in Health and Disease

---

1. Genetic variation can explain why patients may be susceptible to certain illnesses. Cystic fibrosis is an example of how variation in a gene is associated with disease. Which of the following statements is true?

A. Environmental influences are always more important than genetic influences in explaining the susceptibility to illness.

B. Most human diseases are associated with variation in a single gene (monogenic traits).

C. Most human illnesses follow Mendelian patterns of inheritance.

D. The development of hypertension is a complex trait that is influenced by multiple genes.

Preferred response: D

Rationale

In human beings, monogenic traits are relatively uncommon. Most traits are complex and are influenced by multiple genes. Hypertension is a good example of a complex trait. Response A is false because both genetic and environmental influences are important in determining susceptibility to illness.

2. Investigators are interested in identifying genes that are associated with a poor outcome in sepsis. To answer this question, they conduct a genome-wide association study (GWAS) on a group of 30 children with sepsis in a pediatric intensive care unit. For the sample analysis, the investigators choose a platform that genotypes 100,000 single nucleotide polymorphisms (SNPs) in each study participant. A statistician analyzes the data to determine if any SNPs are associated with poor outcome (death, tissue loss, prolonged hospitalization). Which of the following statements is true?

A. Because so many SNPs are being tested, this investigation will have a high likelihood of identifying all the genetic variants that are associated with a poor outcome in sepsis.

B. GWASs have a high risk of type II error. This should be considered in the study design.

C. If an SNP is found to be associated with an increased risk of death, this SNP is the genetic variant that is responsible for the increased risk.

D. The risk of death with sepsis, as is the case with most human disease, is likely attributable to variation in a single gene.

Preferred response: B

Rationale

Because many SNPs are tested in a typical GWAS, the power of this study is greatly reduced as a result of multiple hypothesis testing. Consequently, GWASs must usually enroll large numbers of patients if they are to have an adequate power to detect SNPs associated with a disease phenotype. Different ancestral populations often differ substantially in the frequency of SNP sites and SNP alleles. Consideration of ancestry is very important in interpreting GWASs and in applying the results of the studies to other populations. Sepsis, like most human diseases, is a complex trait that is influenced by multiple genes.

3. A 4-month-old patient who was born 2 months prematurely was discharged from the hospital 1 month after birth but has had continued respiratory problems unrelated to infection and is currently admitted to the pediatric intensive care unit. A lung biopsy has been performed and shows aberrant lamellar bodies. Genetic testing (from a blood sample) has shown that the child is homozygous for a specific genetic variation (a single nucleotide polymorphism) in a noncoding regulatory region of the surfactant protein B gene. Which of the following interpretations is most likely?

A. The genetic variation cannot explain the aberrant lamellar bodies and respiratory distress because it is in a noncoding region of the gene.
B. The genetic variation is likely the explanation for the aberrant lamellar bodies and respiratory distress because the variation results in a change in one of the amino acids in the surfactant protein B protein.
C. The genetic variation may be the explanation for the aberrant lamellar bodies and respiratory distress because the variation is in a regulatory region of the gene and may affect the level of surfactant protein B made in the cell.
D. The genetic variation is unimportant because it was derived from a blood sample and not lung tissue.

Preferred response: C

Rationale

Because the genetic variation is in a noncoding region of the surfactant protein B gene, it does not result in an amino acid change in the surfactant B protein. However, it is in a regulatory region that could affect the level of surfactant protein B made by alveolar epithelial cells. The deoxyribonucleic acid (DNA) sequence is the same in all cells in the body, so the genetic variation will also be present in all cells in the child, but its only potential impact is in cells that are making the surfactant protein B protein.

4. Which of the following statements is correct regarding DNA arrays?
   A. DNA arrays have been used successfully in research but have yet to be utilized diagnostically in clinical medicine.
   B. DNA arrays can be configured to genotype single nucleotide polymorphisms, copy number variants, or determine the relative expression of specific genes (gene expression arrays).
   C. DNA arrays can be used to quantitate protein levels.
   D. DNA arrays are very limited in the number of genes or single nucleotide polymorphisms that can be examined on one array.

   Preferred response: B

Rationale

DNA arrays have been used to examine single nucleotide polymorphisms, copy number variants, and determine gene expression (which includes examining gene expression changes in children with sepsis). Such arrays are used not only in research studies but also diagnostically (particularly for certain cancer types). One advantage of DNA arrays is that thousands to millions of genes or genetic variations can be examined on a single array.

Chapter 84: Molecular Foundations of Cellular Injury: Apoptosis and Necrosis

1. Which of the following is correct regarding lymphocyte apoptosis?
   A. Lymphocyte apoptosis results in immune suppression through altered effector cell function and impaired immune responses.
   B. Lymphocyte apoptosis results in a hyperinflammatory response.
   C. Mechanisms of apoptosis vary greatly depending on the cell type involved.
   D. Prevention of lymphocyte apoptosis does not change mortality in septic animals with underlying malignancy.
   Preferred response: A

Rationale

Apoptosis results in immune suppression, and prevention of this consequence in the setting of critical illness can restore immunity and immune response. Apoptosis is a conserved cell death pathway that is initiated by an extrinsic and intrinsic pathway regardless of the cell type involved. Prevention of lymphocyte apoptosis worsens mortality in septic cancer mice. Lymphocyte apoptosis results in a hypoinflammatory state of immune suppression.

2. Which of following is true regarding autophagy?
   A. Autophagy is random and is an intermediate step to apoptosis.
   B. Autophagy results in a loss of important cell functions.
   C. Autophagy is an adaptive response during times of stress.
   D. Autophagy increases during critical illness and contributes to sepsis mortality.
   Preferred response: C

Rationale

Autophagy is an adaptive response and can prevent cell death and allow cell survival during times of stress. Activation of the autophagic response is directed at preventing cell death and apoptosis. Autophagy removes superfluous cellular components, which may or may not result in a loss of functions. There is a decline in autophagic responses during sepsis, and restoration of these functions can improve mortality. Autophagy has been demonstrated in multiple organ systems including the heart, lungs, liver, kidneys, and immune system.

3. Which of the following morphologic characteristics is associated with apoptosis?
   A. Double membrane vesicles
   B. Early loss of membrane integrity associated with an inflammatory response
   C. Organelle shrinkage and nuclear fragmentation without inducing an inflammatory response
   D. Organelle swelling and random deoxyribonucleic acid (DNA) fragmentation
   Preferred response: C

Rationale

Apoptosis (also known as programmed cell death type I or “cell suicide”) is a well-

controlled, evolutionarily conserved process. Following an appropriate trigger, a cell's apoptotic machinery leads to orderly death of the cell, which is characterized by cell and organelle shrinkage (pyknosis), nuclear fragmentation (karyorrhexis), and cytoplasmic blebbing with retention of plasma membrane integrity. Ultimately the cell is fragmented into small apoptotic bodies that are phagocytosed by neighboring cells. Orderly DNA fragmentation is identifiable on electrophoretic gels as a characteristic ladder pattern. Because cytosolic contents are not released into the interstitial space, there is no accompanying inflammatory response.

Chapter 85: Common Endocrinopathies in the PICU

---

1. A 2-year-old admitted to the PICU with prolonged septic shock is found to have an elevated reverse T3 and normal thyroid-stimulating hormone. Which of the following proteins is primarily responsible for these findings?

   A. Iodotyrosine deiodinase

   B. Sodium-iodide transporter

   C. Thyroid oxidase

   D. Thyroglobulin synthase

   Preferred response: A

Rationale

In peripheral tissues, thyroxine (T4) is metabolized to triiodotyrosine (T3) and reverse T3 (rT3) by the action of various isoforms of iodothyronine deiodinases. Transcription and translation of this enzyme is highly dependent on cytokine stimulation. Selenocysteine residues characterize the active site of this iodine cleavage enzyme. If monodeiodination occurs on the outer tyrosine ring, the product is T3; if the monodeiodination occurs on the inner tyrosine ring, the resultant product is rT3.

2. A previously healthy 8-month-old child is admitted to a PICU with rhinovirus bronchiolitis and clinical septic shock unresponsive to volume resuscitation and high dose vasoactive-inotropic support. A random total cortisol level is found to be 1 mcg/dL. At autopsy, severely atrophic adrenal glands are noted. History reveals that this child's sibling died under similar circumstances. What is this child's most likely diagnosis?

   A. Cortisol-binding protein deficiency

   B. Mutation involving 11β-hydroxylase (CYP 11B1)

   C. Mutation involving the type 2 melanocortin receptor.

   D. Single nucleotide polymorphism for 21-hydroxylase (CYP-21)

   Preferred response: C

Rationale

In hypothalamic-pituitary-adrenal (HPA) axis signaling for the sepsis-induced stress response, adrenocorticotropic hormone (ACTH) is transported by the blood to the zona fasciculata of the adrenal gland where it normally binds to type 2 melanocortin receptors (MC2R) to initiate steroidogenesis. Familial cortisol deficiency is a lethal condition associated with hypoplastic adrenal glands and is caused by a mutation in the MC2R that impairs ACTH signaling.

3. For which of the following adverse events has a significantly increased risk been documented for children receiving postoperative corticosteroids following cardiovascular surgery?

   A. Hospital-acquired infections

   B. Hypoglycemia

   C. Lean body catabolism

   D. Posttraumatic stress disorder

   Preferred response: A

Rationale

Two investigations have demonstrated an increased risk of hospital-acquired infections among critically ill children, one examining a general PICU population and one examining a cardiac intensive care (CICU) population. This finding is concordant with known corticosteroid repression of all aspects of adaptive immunity. Prolonged, high-dose corticosteroid administration would be expected to be associated with increased lean muscle catabolism, posttraumatic stress disorder, and transition to delirium (in adults), but these events have not been specifically studied in children undergoing cardiac surgery. Other adverse events associated with corticosteroids include hypertension, hypernatremia, hyperglycemia (not hypoglycemia), and hypokalemia.

4. In an acutely critically ill child, which of the following hormones is typically released concurrently with corticotropin-releasing hormone from the hypothalamus?

   A. Leptin

   B. Somatostatin

   C. Thyroid-releasing hormone

   D. Vasopressin

   Preferred response: D

Rationale

Various stimuli converge on the paraventricular nucleus of the hypothalamus resulting in the release of corticotropin-releasing hormone (CRH). Similar stimuli also increase the release of antidiuretic hormone (ADH), arginine vasopressin. Somatostatin is activated by growth hormone. Leptin is produced in adipose tissue. Thyroid-releasing hormone is produced in the hypothalamus to facilitate the release of thyroid-stimulating hormone from the anterior pituitary.

5. A critically ill previously healthy toddler exhibits presumed stress hyperglycemia

of 150 mg/dL 2 days following a fall from a second-story window resulting in multiple traumas. Which of the following precursors is an unlikely source molecule for glucose production at this time?

A. Alanine

B. Glycogen

C. Glycerol

D. Lactate

Preferred response: B

Rationale

Alanine and glutamine can be mobilized from lean body muscle following activation of atrogene pathways by cortisol. These amino acids are transaminated to pyruvate and oxaloacetate, respectively, and shuttled into the gluconeogenesis pathway. Lactate can be oxidized to pyruvate, which is then a substrate for gluconeogenesis. Glycerol, the three-carbon backbone for triglycerides, is derived following hydrolysis of three fatty acids and may be phosphorylated to glycerol-3-phosphate, another substrate for gluconeogenesis. Two days following injury and activation of the stress response, liver glycogen stores would be depleted and accordingly glycogenolysis would not be an active participant in glucose production.

6. A 2-year-old sustains a 20% scald burn and is admitted to a PICU. Which of the following is an aspect of the neurogenic-endocrine-inflammation stress response that will be associated with this injury?

A. Increased parasympathetic activity to increase glycogenolysis

B. Increased adrenocorticotropin hormone (ACTH) to increase potassium reabsorption

C. Increased antidiuretic hormone to increase sodium reabsorption

D. Increased glucagon to increase glycogenolysis

Preferred response: D

Rationale

Increased sympathetic activity, not parasympathetic activity, promotes glycogen breakdown; cortisol augments gluconeogenesis; antidiuretic hormone augments water, not sodium reabsorption; and increased ACTH ultimately would lead to enhanced sodium reabsorption, not potassium reabsorption, via the mineralocorticoid activity of cortisol.

7. A previously healthy 5-year-old child is admitted to a PICU with *Streptococcus pneumoniae* sepsis and exhibits hypotension despite volume resuscitation to a central venous pressure of 12 mm H_2O and prescription of an epinephrine infusion at 0.6 mcg/kg/min. Because of hypotension, the patient was sedated with etomidate in the emergency department to facilitate endotracheal intubation. A random total cortisol level is found to be 5 mcg/dL. What best explains this patient's recalcitrant unstable hemodynamic status?

A. Elevated circulating transcortin and albumin

B. Excess neutrophil elastase at inflammation foci

C. Inactive 11β-hydroxylase (CYP 11B1)

D. Low circulating ACTH

Preferred response: C

Rationale

A single dose of etomidate inhibits 11β-hydroxylase (CYP-11B1), a rate-limiting step in cortisol biosynthesis, has been shown to be an independent risk factor for sepsis-related mortality. Both transcortin and albumin would likely be low in this scenario. Excess neutrophil elastase would increase free cortisol at sites of inflammation. ACTH would be expected to be elevated in this situation.

8. A 2-year-old child who is recovering from sepsis and has newly diagnosed acute lymphoblastic leukemia has received methylprednisolone, 1 mg/kg, administered intravenously every 6 hours for 2 weeks. Which of the following would be an expected related adverse effect of the corticosteroid?

A. Hyperkalemia

B. Hyperuremia

C. Hyponatremia

D. Hypotension

Preferred response: B

Rationale

Prolonged, high-dose corticosteroid administration would be expected to be associated with increased lean muscle catabolism, which would generate alanine and glutamine substrate for gluconeogenesis. This situation would lead to an increased production of blood urea nitrogen (hyperuremia) as a result of enhanced transamination of alanine and glutamine, thus generating pyruvate and oxaloacetate. Other adverse effects of the corticosteroids might include hypertension, hypernatremia, hyperglycemia, and hypokalemia, in addition to an increased risk of hospital-acquired infection.

9. In a critically ill child who has had cardiac surgery, which of the following biochemical events would be expected to be associated with documented stress hyperglycemia?

A. Decreased circulating insulin concentrations

B. Decreased activation of NF-κB

C. Increased complement fixation by IgG and binding

D. Increased lymphocyte glucose uptake

Preferred response: D

Rationale

Despite the hyperglycemia, circulating insulin concentrations would be elevated in this stress scenario. Despite peripheral insulin resistance, stress increases whole body glucose uptake, which occurs at the expense of non–insulin-dependent tissues,

especially those involved in the immune response. Cytokines have been shown to up-regulate the expression of GLUT-1 and GLUT-3, which place non–insulin-dependent tissues at risk for direct glucose toxicity in the presence of elevated plasma glucose levels. Hyperglycemia is associated with increased mitochondrial production of peroxynitrite, enhanced activation of NF-κB, and impaired complement fixation by IgG and binding to the microbial surfaces.

10. A 9-month-old previously healthy child exhibits serum glucose of 170 mg/dL 1 day following a fall from a second-story window resulting in a cerebral contusion and displaced right humerus fracture. In this setting, which of the following molecules would fail as a potential gluconeogenesis precursor?

    A. Alanine

    B. Glycerol

    C. Glutamine

    D. Palmitate

    Preferred response: D

Rationale

Alanine and glutamine can be transaminated to pyruvate and oxaloacetate, respectively, and shuttled into the gluconeogenesis pathway. Lactate can be oxidized to pyruvate, which is then a substrate for gluconeogenesis. Glycerol, the three-carbon backbone for triglycerides, is derived following hydrolysis of three fatty acids and may be phosphorylated to glycerol-3-phosphate, another substrate for gluconeogenesis. No net glucose production can be achieved from fatty acids—for example, palmitate—although β-oxidation of fatty acids generates adenosine triphosphate, which is required for gluconeogenesis.

11. An otherwise healthy child is recovering in a PICU following a switch operation for transposition of the great vessels. No surgical or anesthetic complications occurred. Mechanical ventilation was discontinued, and the child was tracheally extubated 12 hours following PICU admission. The patient has required no vasoactive-inotropic support. On day 2 following surgery, a serum triiodothyronine (T3) level is found to be significantly decreased. Which of the following thyroid test results would also be expected?

    A. Decreased total thyroxine (T4)

    B. Decreased reverse T3

    C. Increased free thyroxine (T4)

    D. Normal thyroid-stimulating hormone

    Preferred response: D

Rationale

Laboratory characteristics of sick euthyroid syndrome, the likely diagnosis is this hemodynamically stable child, include normal total T4 and free T4; markedly reduced T3 resulting from decreased peripheral conversion of T4 to T3 because of decreased 5′-deiodinase activity; a variable increase in reverse T3; a variable decrease in thyroid-hormone binding proteins, including transthyretin; and a normal

thyroid-stimulating hormone level, indicating the absence of true hypothyroidism.

Chapter 86: Diabetic Ketoacidosis

1. A 14-year-old female is admitted with diabetic ketoacidosis; initial blood glucose is 690 mg/dL, β-hydroxybutyrate (BOHB) is 4 mmol/L, and venous blood pH is 7.19. She received a 10-mL/kg bolus of physiologic saline. A continuous intravenous insulin infusion of 0.1 unit/kg/hour was initiated in addition to intravenous fluids (NS with potassium chloride and potassium phosphate). The follow-up glucose level after 2 hours is 239 mg/dL. What is the next best step in the management of this child?

   A. Change to subcutaneous insulin therapy with glargine.

   B. Give 10% dextrose bolus.

   C. Introduce dextrose-containing fluid, preferably with the two-bag system.

   D. Reduce the insulin infusion rate to 0.05 units/kg/hour.

   Preferred response: C

Rationale

Following fluid resuscitation with 0.9% saline solution bolus, initiation of fluid and insulin therapy may result in a rapid decrease of glucose level. Introducing intravenous dextrose in the rehydration fluid or using the two-bag system is the best next step to avoid further glucose decrease and provide substrate (glucose) while continuing insulin therapy to clear ketones.

Advantages of the two-bag system are as follows:

(1) Uses the simultaneous administration of two intravenous fluid bags each with identical electrolytes, but one bag contains 10% dextrose and the other does not

(2) Empowers the bedside nurse to adjust the infusion rate of each bag to address fluctuations in the patient's serum glucose without altering the insulin rate

(3) Reliably meets the changing glucose of a child with DKA on an insulin drip

(4) Prevents waiting for rehydration fluid decisions, pharmacy delivery, and nurse administration

(5) Relies on a calculation of percentage of fluids to be administered based on the fluid administration rate

2. What is the best marker for readiness to transition from a continuous insulin infusion in diabetic ketoacidosis (DKA) to subcutaneous insulin therapy?

   A. β-hydroxybutyrate (BOHB)

   B. Closure of anion gap

   C. Hypoglycemia onset

   D. Serum bicarbonate level

   Preferred response: A

Rationale

With prolonged use of concentration higher than 0.45% saline solution rehydration fluid regimens may lead to hyperchloremia resulting in persistent base deficit or low serum bicarbonate concentrations; hyperchloremic acidosis may be misinterpreted as ongoing ketoacidosis. To prevent this misinterpretation, BOHB should be used as a marker of resolution of DKA. Anion gap may be useful to track resolution of acidosis, but it is unable to differentiate a mixed metabolic acidosis (hyperchloremic and ketotic), and the degree of hyperchloremic acidosis is not quantifiable.

Utilization of BOHB is as follows:

(1) BOHB levels should be monitored every 2 hours until <1 mmol/L.

(2) There are two major ketone bodies that cause acidosis in DKA: BOHB and acetoacetate. BOHB is the predominant ketone body in DKA but is not detected with urine ketone measurements. Acetoacetate is detected in urinary ketone measurements. Acetone, which results in fruity-smelling breath, does not contribute to acidosis.

(3) BOHB levels represent the best indicator of ketosis and resolution of DKA.

(4) BOHB levels reflect the impact of fluid resuscitation and insulin administration on the child's ketosis; as pH and PCO_2 levels increase, BOHB levels decrease.

(5) Bedside BOHB meters can provide real-time results to dictate treatment changes, simultaneously with bedside electrolyte, blood gas, and glucose measurements.

(6) Use of site-of-care BOHB testing has been associated with decreased PICU length of stay and laboratory costs.

(7) Normalization of BOHB levels is a strong indicator for transition to subcutaneous insulin. Discontinue the insulin drip and begin subcutaneous insulin when BOHB is <1 mmol/L.

3. What hydration fluid should be used in the first 4 to 6 hours when managing diabetic ketoacidosis?

A. Albumin-containing fluids

B. 0.45% saline solution

C. 0.9% saline solution

D. 10% dextrose

Preferred response: C

Rationale

The most critical time period of fluid therapy is the first 4 to 6 hours, during which time isotonic fluid should be used to reduce the risk of cerebral edema.

4. What is the most frequent cause of diabetic ketoacidosis (DKA) in children with known diabetes?

A. Excess sugar consumption

B. Gastroenteritis

C. Insulin omission

D. Urinary tract infection

Preferred response: C

Rationale

Insulin omission, either accidental or intentional, is the most common cause of DKA in children. Fewer than 30% of DKA episodes in children are caused by infections or other illnesses.

5. The serum glucose concentration declines to 150 mg/dL in a child undergoing treatment for DKA. The child is receiving insulin at 0.1 units per kilogram per hour and a 0.9% saline solution infusion. The serum pH is 7.19, and urine ketones are large. What is the best response?
   A. Change to intravenous fluids that contain dextrose.
   B. Decrease the insulin infusion to 0.03 units/kg/hour.
   C. Increase the insulin infusion to 0.15 units/kg/hour.
   D. Increase the rate of infusion of 0.9% saline solution.
   Preferred response: A

Rationale

DKA results from relative or absolute insulin deficiency. When serum glucose is beginning to normalize but metabolic acidosis or β-hydroxybutyrate persists, dextrose should be added to the intravenous fluids instead of decreasing the insulin infusion. During treatment for DKA, the serum glucose concentration frequently declines into the normal range before resolution of ketosis. At this stage it is important to continue an optimal rate of insulin infusion to allow full resolution of ketosis. Insulin therefore should be continued at 0.1 unit/kg/hour and glucose should be added to the intravenous fluids to prevent hypoglycemia.

Chapter 87: Nutrition in the Critically Ill Child

---

1. Which of the following statements about protein during critical illness is true?
   A. Adequate energy and protein delivery attenuates protein breakdown in critically ill patients.
   B. One gram of protein yields 8 cal of energy.
   C. Protein synthesis and breakdown increase during critical illness.
   D. Protein synthesis and breakdown decrease during critical illness.
   Preferred response: C

Rationale

Protein catabolism (breakdown) is a characteristic feature of critical illness. Although protein synthesis may be increased, it is often not enough to offset protein losses and results in a net negative protein balance. Adequate energy and protein intake will help optimize synthesis and balance the catabolism, but it does not attenuate the protein breakdown.

Studies have shown that protein requirement during critical illness in children may be higher than 1.5g/kg/day; 1 gram of protein/amino acid provides 4 kcal of energy; 1 gram of carbohydrate provides 4 kcal; and 1 gram of lipid/fat provides 9 kcal.

2. Which of the following statements about enteral nutrition (EN) is true?

A. Enteral nutrition is contraindicated in patients receiving vasoactive medications.

B. Gastric residual volume (GRV) is an accurate measure of EN intolerance.

C. Parenteral nutrition is preferred to enteral nutrition in patients on extracorporeal membrane oxygenator therapy.

D. Postpyloric enteral feeding may be used in patients at risk of gastric aspiration.

Preferred response: D

Rationale

EN is the preferred mode of nutrient delivery in critically ill children. In patients with a functional gastrointestinal tract, early initiation of EN is preferred. Careful selection of patients and use of bedside protocols help guide EN delivery in the PICU. PN may be considered in patients where EN is contraindicated or where it has been not tolerated or failed to meet the nutrition goals. Gastric route is preferred. Postpyloric feeding may be used in patients eligible for EN, when gastric feeding is not tolerated or when aspiration risk is high.

GRV on its own is not an accurate marker of EN intolerance. Enteral nutrition may be initiated in patients who are on inotropic support, after hemodynamic stability has been achieved and there is not further fluid resuscitation of escalation in vasoactive therapy. Multiple studies have demonstrated tolerance and successful use of EN in this group of patients.

Chapter 88: Structure and Function of Hematopoietic Organs

---

1. A 2-year-old African-American boy is transferred to the PICU from an outside ER with a history of high fevers and hypotension. His initial blood pressure was 50/30 mm Hg, and this improved to 80/50 mm Hg following a fluid bolus. His white blood cell count is 25,000/mm^3 with a "shift to the left" of granulocytes, hemoglobin 7 g/dL, and platelets 60,000/mm^3. The reticulocyte count is 10% and total bilirubin is 6 mg/dL, mostly indirect or unconjugated. An arterial blood gas shows moderate lactic acidosis, and a DIC screen shows a PTT of 48 seconds, INR of 1.8, D-dimers of 1000 ng/mL, factor VIII of 20 U/mL, and factor V of 30 U/mL. He has had one dose of ceftriaxone at the outside hospital. What is the most likely diagnosis?

A. Acute lymphocytic leukemia

B. Bleeding due to hemophilia A, and recombinant factor VIII should be administered

C. Liver failure with bleeding and a secondary marrow response to bleeding; transaminase levels should be obtained and transplant surgery consulted

D. Sepsis; broadened antibiotics are indicated with further adjustments based on history, physical examination, and blood culture results

Preferred response: D

Rationale

This child has sepsis until proved otherwise. Further history should be obtained when the family arrives to see if there is an underlying reason for sepsis such as sickle cell disease or asplenia. Hemophilia A does result in increased PTT levels but should not affect coagulation factors other than factor VIII. Although boys with hemophilia may become septic, especially if they have a central line in place, recombinant replacement factor should not be given in the absence of a specific diagnosis. Although liver failure will produce altered coagulation factors, factor VIII (which is made by endothelial cells all over the body and not just in the liver) is differentially spared. Based on the indirect hyperbilirubinemia, it is possible that the child might also have a hemolytic process other than or in addition to DIC, and this would need to be sorted out over time. The child's peripheral smear before transfusions should be evaluated. Although leukemia can present with sepsis, it is not enough by itself to account for this presentation. A differential cell count and evaluation of the child's peripheral smear would help eliminate this concern.

2. A 4-year-old boy is admitted to the ICU following head trauma and a large subarachnoid bleed with midline shift. Complete blood count (CBC) in the ER shows a platelet count of 4,000/mm^3, white blood count of 6,000/mm^3, and hemoglobin of 9 g/dL with normal red cell indices. History is notable only for a mild upper respiratory infection a few weeks ago and recent onset of bruises and gum bleeding. Neurosurgery wants to take the child to the OR immediately to evacuate the bleed. What should you tell the neurosurgeon?

A. Don't treat at all, because there is an increasing understanding that most children with immune thrombocytopenic purpura (ITP) won't need treatment.

B. Go for it, because this is an emergency, and give a platelet transfusion preoperatively.

C. Give platelets immediately preoperatively, have red cells and platelets available for ongoing bleeding, ask the general surgeons to perform a splenectomy immediately prior to or concurrent with the craniotomy, and start intravenous immunoglobulin (IVIG) or prednisone.

D. Start eltrombopag to increase the platelet count and then have the neurosurgeons go for it, because this is an emergency.

Preferred response: C

Rationale

This child almost certainly has ITP, with mild anemia due to recent bleeding. A platelet transfusion may provide transient hemostasis and can be given while other interventions are taking effect. However, transfused platelets will be removed from the circulation as quickly as endogenous platelets. Because craniotomy would

require ongoing hemostasis, splenectomy should be considered as something that is likely to result in a rapid and durable increase in platelets. Intravenous immunoglobulin and corticosteroids may each take several days to work. Not all children will respond to each of these interventions, so one could consider using both at once. Promacta and other “growth factors” also are slower to cause platelet bumps, do not work in everyone, and should be considered to be second line. Any and all of these interventions should be done in consultation with a pediatric hematologist. Although most children with ITP may not need treatment, this is not one of them.

3. Which of the following statements is true about intraosseous infusions (IO)?
   A. Drug and fluid delivery is slower than when given intravenously.
   B. IO is best performed using the humerus.
   C. IO infusion is appropriate when standard intravenous access is not available.
   D. Marrow embolus to the lungs with hypoxemia occurs in 10% of patients getting IO infusions.

   Preferred response: C

Rationale

Unlike peripheral veins, intramedullary vessels supported by their bony shell do not collapse in shock; therefore IO infusion (via either tibial or iliac crest) is appropriate when standard intravenous access is not available. IO infusion ideally should be performed using sterile technique, and even an 18- to 20-gauge short spinal needle or hypodermic needle can be used. Because the marrow circulation interconnects with the general circulation in this fashion, fluids and medication injected in bone marrow are absorbed as rapidly as through intravenous routes. Although the interconnection between the marrow and general circulation provides the mechanism by which bone marrow may embolize to the lung after osseous trauma or fracture, this phenomenon has not been demonstrated to be of clinical significance in the case of IO infusion.

4. Universally accepted recommendations for prevention of infections in neutropenia include which of the following?
   A. Changing sites of percutaneous lines every 24 hours
   B. Reverse isolation
   C. Strict handwashing
   D. Use of prophylactic antibiotics

   Preferred response: C

Rationale

The use of prophylactic antibiotics and reverse isolation is not fully evidence based and will vary among centers and divisions within centers. Recommendations generally do not call for percutaneous lines to be changed more often than every 48 hours, and many recommendations allow peripheral lines to remain in place for as long as a week. Recombinant growth factors are recommended in limited situations, and their use should be discussed with hematology consultants.

5. The life span of a red blood cell (RBC) in a normal adult or older child is approximately how many days?

A. 30 to 60

B. 60 to 90

C. 90 to 100

D. 100 to 120

Preferred response: D

Rationale

Once in the peripheral blood, the life span of the normal RBC in an adult or older child is 100 to 120 days.

6. The life span of an RBC in a term newborn is approximately how many days?

A. 30

B. 60

C. 90

D. 120

Preferred response: B

Rationale

In a term newborn, the RBC life span is about 60 days, and this life span grows progressively shorter with increasing prematurity. It may be that differences in age-dependent RBC longevity reflect differences in membrane stability and oxidative metabolism.

7. The average platelet life span is approximately how many days?

A. 3 to 4

B. 7 to 10

C. 15 to 25

D. 30 to 45

Preferred response: B

Rationale

The average platelet life span is 7 to 10 days.

8. The average life span of granulocytes is approximately how long?

A. 2 hours

B. 12 hours

C. 24 hours

D. 3 days

Preferred response: B

Rationale

The average life span of granulocytes is less than 12 hours.

9. Quantification of reticulocytes provides a rough estimate of the rate of erythropoiesis during the past how many hours?

   A. 24 hours

   B. 48 hours

   C. 72 hours

   D. 96 hours

   Preferred response: A

Rationale

Because reticulocytes lose their ribonucleic acid within 24 to 30 hours when they are extruded into the circulation, their quantification provides a rough estimate of the rate of erythropoiesis during the past 24 hours.

10. In a healthy older child or adult, what is the proportion of myeloid precursors to erythroid precursors in a bone marrow aspirate?

   A. 1 : 2

   B. 1 : 3

   C. 2 : 1

   D. 3 : 1

   Preferred response: D

Rationale

In an older child or adult, erythroid precursors normally are one-third as plentiful as myeloid precursors (ie, the myeloid/erythroid [M/E] ratio is approximately 3 : 1).

11. Which is the major site of erythropoietin production in the fetus?

   A. Bone marrow

   B. Kidneys

   C. Liver

   D. Spleen

   Preferred response: C

Rationale

Erythropoietin is mainly produced in the liver during fetal development, but this site later shifts to the juxtamedullary region in the kidneys.

12. Approximately what percentage of total body platelet mass is normally sequestered in the spleen?

   A. 10%

   B. 15%

   C. 25%

   D. 30%

Preferred response: D

Rationale

Normally one-third of the total body platelet mass is sequestered in the spleen, although the number can go as high as 90% in pathologic states.

Chapter 89: Erythron in Critical Illness

---

1. The oxyhemoglobin dissociation curve describes the relationship between oxygen availability in solution (partial pressure, PO_2) and binding to hemoglobin (% saturation, $HbSO_2$). This affinity relationship changes in response to biochemical cues, resulting in an increase (left shift) or decrease (right shift) in affinity. Which of the following statements about this physiology is true?
   A. Affinity is caused by ↑ temperature, ↓ pH, ↑ pCO_2, ↑ [2,3-DPG].
   B. Affinity is caused by ↓ temperature, ↑ pH, ↓ pCO_2, ↑ [2,3-DPG].
   C. Affinity is caused by ↑ temperature, ↓ pH, ↑ pCO_2, ↑ [2,3-DPG].
   D. Affinity is caused by ↓ temperature, ↓ pH, ↑ pCO_2, ↑ [2,3-DPG].
   Preferred response: C

Rationale

Hemoglobin oxygen affinity is affected by molecules (termed *allosteric effectors*) that increase conformational stability of deoxyhemoglobin; the major effectors are protons (eg, pH, CO_2, 2,3-DPG). When the concentration of these molecules increases, deoxyhemoglobin is stabilized, O_2 affinity decreases, and O_2 delivery is enhanced by facilitating release from red blood cells during tissue perfusion. Increasing temperature—for example, during exercise—also reduces O_2 affinity by directly reducing the strength of the association between O_2 and heme itself.

2. Hypoxic vasodilation maintains the coupling between dynamic variation in tissue oxygen consumption and delivery. How is this key physiologic reflex achieved?
   A. Endothelial nitric oxide synthase (eNOS) locally as a response to tissue PO_2
   B. Red blood cell capture, transport, and release of adrenalin in a fashion that is regulated by hemoglobin conformation
   C. Red blood cell capture, transport, and release of nitric oxide (NO) in a fashion that is regulated by hemoglobin conformation
   D. Sympathetic nervous system responses to stress
   Preferred response: C

Rationale

Hypoxic vasodilation is a key physiologic reflex that ensures matching between variation in tissue O_2 consumption in space (eg, during walking the leg muscles consume more oxygen than neck muscles) and in time (eg, during walking the leg muscles consume more oxygen than during rest). This reflex links tissue pO_2 to vessel caliber; when tissue pO_2 falls, resistance vessels dilate, increasing blood flow, raising pO_2, and resolving O_2 delivery lack. The sensor and effector for this reflex is hemoglobin itself. During tissue perfusion, the vasodilator nitric oxide (NO) is dispensed (exported) from deoxygenating red blood cells in direct proportion to oxygen; therefore in vascular beds with intense oxygen extraction, NO bioavailability is increased, leading to vasodilation and improved blood flow.

3. Acquired loss of function by red blood cells (increased adhesion, decreased deformability, increased aggregation, increased clearance, altered O_2 affinity, altered vasoregulation) during critical illness may lead to progression of organ failure by impairing O_2 delivery. What causes red blood cell failure to arise?

   A. Dysregulation in red cell maturation during erythropoiesis

   B. Effect of cytokine storm upon key signaling pathways

   C. Impaired anaerobic glycolysis and weakened antioxidant systems

   D. Uncoupling of the mitochondrial electron transport chain

   Preferred response: C

Rationale

Red blood cells require a constant energy supply to power antioxidant defense systems. Oxidative stress accompanies most forms of critical illness and strains these systems in red cells. Red cell antioxidant systems in red cells are powered by simple anaerobic glycolysis, which supplies the reducing equivalents needed to repair oxidized structural and functional cellular elements. When these elements suffer oxidative modification and are not repaired, red cell performance is adversely impacted, resulting in increased adhesion, decreased deformability, increased aggregation, altered O_2 affinity, and altered vasoregulation.

Chapter 90: Hemoglobinopathies

1. Which of the following characteristics is typical of children with β-thalassemia?
   A. Acute chest syndrome
   B. Macrocytic anemia
   C. Thickening of the cortex of long bones
   D. Thrombotic events
   Preferred response: D

Rationale

The sine qua non for diagnostics for thalassemia is a microcytic anemia with the demonstration of an α- to β-globin chain imbalance; however, this is not practical for routine testing. Most clinical laboratories rely on a variation of a thalassemia screen. The screen helps distinguish thalassemia from iron deficiency, and α- from β-thalassemia.

In thalassemia, free globin chains increase reactive oxygen species, whereas decreased glutathione and antioxidant stores result in oxidative damage to the fragile red cell membrane, as well as to apoptosis in a Fas-mediated process. The result is a cadre of processes contributing to the heterogeneity of disease presentation. Phosphatidyl serine moves to the outer leaf of the red cell membrane, enhancing macrophage-mediated destruction in the spleen and marrow and acting as a substrate for factor V and VIII binding, enhancing the generation of thrombin, which together with decreased protein C and S levels and increased platelet activation and adhesion leads to increased thrombosis. In an attempt to compensate for the hemolysis and ineffective erythropoiesis, medullary and extramedullary erythropoiesis leads to skeletal abnormalities such as the thalassemic facies and thinning of the cortex of long bones, which, along with endocrine abnormalities, lead to increased fractures. High levels of nontransferrin-bound iron from red cell destruction, increased intestinal absorption from inappropriately low levels of hepcidin, and transfusions lead to iron deposition, resulting in liver, cardiac, and endocrine dysfunction.

Although previous focus was on hepatic iron overload and cirrhosis, there is increasing awareness of iron overload in the heart, pituitary, and endocrine organs leading to dysfunction (the following section), and excessive melanin production leading to "bronze" pigmentation. Cardiac failure due to iron overload, defined as a low ejection fraction with a component of cardiomyopathy, is the major cause of ICU admission and death in thalassemic patients. A thalassemic patient in failure should be assumed to have cardiac iron overload until proved otherwise. Risk factors include transfusion history and underchelation. Untreated overload can also lead to dysrhythmias including atrial fibrillation and ventricular tachycardia, as well as conduction disturbances and heart block.

2. Which of the following two life-threatening complications of sickle cell disease can present with subtle manifestations?
   A. Acute chest syndrome and aplastic crises
   B. Acute chest syndrome and pulmonary hypertension
   C. Multiorgan failure and acute chest syndrome
   D. Vasoocclusive events and aplastic crises

Preferred response: B

Rationale

Although all of the listed complications can be life threatening, multiorgan failure, vasoocclusion, aplastic crisis, and splenic sequestration tend to be associated with significant laboratory findings, signs, or symptoms. Whereas acute chest syndrome (ACS) and pulmonary hypertension can present with dramatic findings, they also can be diagnosed despite a normal physical examination and laboratory findings and subtle symptoms.

3. What underlying process must be aggressively assessed and treated when a thalassemic patient presents in cardiac failure?

   A. Anemia

   B. Iron overload

   C. Myocarditis

   D. Pulmonary hypertension

   Preferred response: B

Rationale

Because of transfusional iron and increased gastrointestinal absorption, virtually all thalassemic patients have iron overload. Iron overload is either one major factor or the major factor contributing to cardiac failure in persons with thalassemia. Aggressive treatment with chelation can rapidly reduce iron overload, significantly improving cardiac function.

4. Which of the following processes is a potent inhibitor of hemoglobin S polymerization and resultant sickling?

   A. Acidosis

   B. Dehydration

   C. Hemoglobin F

   D. Hypoxia

   Preferred response: C

Rationale

Hemoglobin S is a soluble compound when oxygenated. However, when oxygen tension decreases at the tissue level, oxygen is released from the hemoglobin molecule, causing polymerization or aggregation of the molecule and production of gels or crystals inside the cell. Crystallization is enhanced by a high hemoglobin concentration, low pH, and low temperature. A key determinant of sickling is the capillary transit time. The longer a red cell is exposed to the relatively deoxygenated, cold, and acidotic environment of the capillary and postcapillary venule, the more time exists for hemoglobin S polymerization. Hemoglobins F and A_2 are potent inhibitors of hemoglobin S polymerization.

5. Which of the following is the first process responsible for the initiation of a

vasoocclusive crisis in a child with sickle cell disease?

A. Endothelial activation

B. Interaction of sickle erythrocytes with leukocytes

C. Recruitment of leukocytes

D. Vascular occlusion

Preferred response: A

Rationale

Vasoocclusion can be described as a four-step process starting with endothelial activation, which can be triggered by several processes, including the generation of oxygen radicals, adhesion, and infection. These various activating factors can induce expression of the endothelial adhesion molecule and, in step 2, promote the recruitment of adherent leukocytes. In step 3, sickle erythrocytes interact with adherent leukocytes, and in step 4 they cause vascular clogging.

6. Which of the following conditions is the most common cause of hospitalization and death in patients with sickle cell disease?

A. Aplastic crisis

B. Acute chest syndrome

C. Hemolysis

D. Splenic sequestration

Preferred response: B

Rationale

Acute chest syndrome (ACS) is the number one cause of death and hospitalization among patients with sickle cell disease. It is defined as fever, cough, wheezing, chest pain, tachypnea in the presence of a new pulmonary infiltrate involving at least one complete lung segment, and no atelectasis on chest radiograph. Several triggers in the pathophysiology of ACS have been identified, including atelectasis, fat embolism, true thromboembolism, and infection.

7. A 10-year-old patient with sickle cell disease presents to your pediatric intensive care unit with acute chest syndrome (ACS). You initiate rehydration, pain control, oxygen, and broad-spectrum antibiotics and decide to transfuse packed red blood cells. What other intervention has been shown to be of benefit in these cases?

A. Aspirin

B. Corticosteroids

C. Bronchodilators

D. Ibuprofen

Preferred response: C

Rationale

Recommendations for treatment of patients diagnosed with ACS consist of general management, which includes adequate pain control, rehydration, and oxygen

administration for patients with pulse oximetry measurements less than 97% or 2% to 3% below baseline. More specific management of ACS consists of (1) use of broad-spectrum antibiotics including a macrolide, (2) use of bronchodilators even if no wheezing is present, (3) transfusion, (4) bronchoscopy for patients who do not respond to initial therapy, and (5) aggressive ventilation or extracorporeal membrane oxygenation. Corticosteroid use remains controversial.

Chapter 91: Coagulation and Coagulopathy in Critical Illness

---

1. A 4-year-old male with known cystic fibrosis presents with a 5-day history of increasing diarrhea and new onset fever, bruising, and bloody diarrhea. Physical exam reveals a thin though otherwise well-appearing child in no acute distress with mild tachycardia but otherwise normal vital signs. Laboratory studies reveal hemoglobin of 9.2 g/dL, a platelet count of 189 × 10^3 per microliter, normal white blood cell count and red blood cell (RBC) morphology, prothrombin time (PT) of 42.6 seconds, and activated partial thromboplastin time (aPTT) of 34.2 seconds. Comprehensive metabolic panel is unremarkable. What is the most likely diagnosis?

   A. Disseminated intravascular coagulation (DIC)

   B. Hemolytic uremic syndrome (HUS)

   C. Liver disease

   D. Vitamin K deficiency

   Preferred response: D

Rationale

The isolated prolonged PT places the defect in the "extrinsic" component of the traditional clotting cascade. The only single clotting factor deficiency that would produce this pattern is a deficiency of factor VII. Factor VII is a vitamin K–dependent clotting factor that requires vitamin K for the posttranslational modification, enabling it to be efficiently activated to activated factor VII (F. VIIa). Vitamin K is a fat-soluble vitamin, and children with cystic fibrosis may not adequately absorb vitamin K from their diet, particularly if they are having increased diarrhea during an exacerbation of their disease. Although the absence of thrombocytopenia and prolongation of the aPTT do not rule out DIC, their absence, along with normal RBC morphology, makes this diagnosis less likely. The normal chemistry profile points against liver disease or HUS.

2. A 12-year-old autistic child is admitted to the PICU following scoliosis repair. The patient was estimated to have a total of 1500 mL of blood loss during the procedure, and he received six units of stored packed red blood cells (RBCs) intraoperatively. Immediately before wound closure he received one unit of fresh frozen plasma (FFP) and one unit of apheresis platelets (equivalent to the platelets derived from eight units of whole blood donation). Upon arrival to the PICU, he was mildly tachycardic but with normal blood pressure. Physical exam

demonstrated bloody surgical dressings but no blood on suctioning of the endotracheal tube. Urine output was >2 mL/kg/hr during and following the surgical procedure (urinary catheter in place); no hematuria was noted. Preoperative weight was 37.5 kg and preoperative hematology evaluation was within normal limits (hemoglobin (Hb), 12.3g/dL; platelets, 221 × 10^3 per microliter; prothrombin time (PT), 11.8 seconds; and activated partial thromboplastin time (aPTT), 32.1 seconds). Laboratory studies obtained in the operating room before transfer to the PICU were as follows: Hb, 11.6 g/dL; platelet count, 88 × 10^3 per microliter; PT, 22.1 sec; aPTT, 47.7 sec; and fibrinogen, 91mg/dL. The patient's mother admits that her son's grandfather had given the boy ibuprofen (400 mg) the evening before because of a headache. What is the most likely cause for this clinical/laboratory picture?

A. Disseminated intravascular coagulation (DIC)

B. Drug-induced platelet defect

C. Liver disease

D. Massive transfusion syndrome

Preferred response: D

Rationale

Intraoperatively, this child received approximately 60% to 65% of his estimated blood volume in the form of stored RBCs. Packed RBCs contain neither platelets nor sufficient amounts of clotting factors to support clot formation. Although he did receive a large platelet transfusion and a single unit of FFP at the end of the procedure, this was not sufficient to reconstitute his hemostatic balance. This syndrome could have been prevented if platelets and FFP were transfused in a ratio of close to 1 : 1 : 1 (RBC : FFP : platelets). Although DIC can develop in the context of massive transfusion, this diagnosis is less likely given the clinical context. Although a markedly increased D-dimer assay might increase the possibility of DIC contributing to the clinical picture, one would expect D-dimer to be elevated in the immediate postoperative period, limiting its usefulness in this setting. The thrombocytopenia would not be explained by an anesthesia-induced hepatic insult or acute exacerbation of underlying liver disease. An acquired (or congenital) platelet defect would not explain the abnormal coagulation parameters present.

Chapter 92: Thrombosis in Pediatric Intensive Care

1. What is the most common cause of thromboembolic disease in children?

A. Factor V Leiden

B. Protein C deficiency

C. Sepsis

D. Vascular access devices

Preferred response: D

Rationale

The most common cause of thromboembolic disease in children is vascular access devices. Protein C deficiency is a rare thrombophilia of childhood. Factor V Leiden mutation, although more common than protein C deficiency, is rarely the primary stimulus for a thromboembolic event. Most often in children it is a multiple hit that results in thrombosis (ie, sepsis + factor V Leiden mutation + vascular access device).

2. In infants, which factor(s) have levels that are 33% to 50% lower than adults?

   A. Antithrombin

   B. Factor II, VII, IX, and X

   C. Factor V, VIII, XIII, and von Willebrand factor

   D. Protein C and protein S

   Preferred response: B

Rationale

Vitamin K–dependent clotting factors are the most studied group of factors in infants. Factors II, VII, IX, and X have been demonstrated to have levels that are 33% to 50% lower in infants than in adults, despite vitamin K prophylaxis at birth. This is a part of the complexity that is developmental hemostasis. Factor V, VIII, XIII, and von Willebrand factor are elevated at birth. Protein C is very low at birth, and protein S is also lower; however, the functional activity of protein S is similar to that of adults, as all of the protein S is in its active free form. Antithrombin is also lower at birth, albeit to a lesser extent than the vitamin K–dependent factors.

3. In a child with a suspected superior vena cava (SVC) syndrome, which of the following is the most appropriate investigation to confirm the diagnosis?

   A. Clinical grounds in conjunction with D-dimers

   B. Clinical grounds in addition to thrombophilia workup

   C. Contrast venography

   D. Ultrasound alone

   Preferred response: C

Rationale

Because venous thrombosis in children is often asymptomatic and many conditions mimic thrombosis, clinical grounds are never sufficient to diagnose venous thrombosis, and thus radiologic confirmation is always required. D-dimers are unhelpful in children, and a thrombophilic workup should never be used to confirm or exclude a diagnosis of thrombosis. Thrombophilia investigations pertain to etiology but never to actual diagnosis of venous thrombosis, which is a radiologic issue. Ultrasound and echocardiography lack both sensitivity and specificity in this circumstance, and hence contrast imaging is required. Currently no data are available to differentiate between traditional venography and computed tomography or magnetic resonance venography, and local expertise and availability will determine the optimal choice.

4. A child who is in the pediatric intensive care unit for airway management and

nutritional support begins bleeding unexpectedly from intravenous sites and mucous membranes. Immediate coagulation studies reveal an activated partial thromboplastin time (aPTT) of >200 seconds, an international normalized ratio (INR) of >5, and a normal fibrinogen level. Results of a full blood examination are normal, with a platelet count of 220,000/μL. What is the most likely cause of the coagulopathy?

A. Accidental heparin overdose

B. Disseminated intravascular coagulation (DIC)

C. Liver disease

D. Platelet function disorder

Preferred response: A

Rationale

Hemophilia and platelet function defects do not prolong the aPTT and INR. Severe liver disease would be associated with a low fibrinogen level. DIC usually occurs in persons with sepsis, severe hypotension, or severe hypoxia, none of which exist in this child. Given that fibrinogen is an acute phase reactant, it is possible to have DIC with a normal fibrinogen level. Accidental heparin overdoses are common in pediatric hospitals because of selection errors. Often the child is meant to be receiving a low-dose heparin line flush that may or may not even be documented in the child's medical record. A massive heparin overdose will prolong both the aPTT and INR in many laboratories, depending on the reagent/analyzer system in place. In any hospitalized child with unexpected severe coagulopathy, accidental heparin overdose should be in the initial differential diagnosis.

Chapter 93: Transfusion Medicine in the Pediatric Intensive Care Unit

---

1. Patients with which of the following would not directly benefit from a red blood cell transfusion?

A. Elevated lactate

B. Hemodynamic instability

C. Low hemoglobin concentration

D. Low PaO_2

Preferred response: D

Rationale

Red blood cell transfusions can be used to improve oxygen delivery (DO_2). Therefore one could justify a decision to transfuse a hemodynamically unstable patient, a patient with low hemoglobin level, a patient with high lactate level, or a bleeding patient by trying to improve DO_2. However, red blood cell transfusions cannot increase low PaO_2 or low SaO_2. Moreover, O_2 consumption does not always increase

in severely ill patients even after the DO_2 is increased.

2. What is the most frequent cause of death attributable to transfusion?
   A. Hemolysis
   B. Transfusion-associated circulatory overload
   C. Transfusion-related acute lung injury
   D. Transfusion-transmitted infectious diseases
   Preferred response: B

Rationale

The risk of bacterial contamination is 1 : 51,136 transfusions, whereas the risk of transfusion-transmitted nonbacterial infection is lower than 1 : 1,000,000 transfusions. Acute hemolytic reaction occurs in 1 : 26,914 transfusions. Transfusion-related acute lung injury (TRALI) is reported in 1 : 31,960 transfusions, whereas transfusion-associated circulatory overload (TACO) is reported in 1 : 34,091 transfusions. Transfusion-associated graft-versus-host disease is reported in less than 1 : 1,000,000. Of these complications, TACO is presently the leading cause of transfusion-related morbidity and mortality in North America, as described by Cohen and associates in the Serious Hazards of Transfusion (SHOT) report.

3. Which of the following results from storage of packed red blood cells (PRBCs)?
   A. Decrease in lactate
   B. Decrease in potassium
   C. Decrease in 2,3-diphosphoglycerate (2,3-DPG)
   D. Shift of oxygen-hemoglobin dissociation curve to the right
   Preferred response: C

Rationale

PRBC units undergo several changes during storage, which are generally referred to as “storage lesions.” RBCs metabolize glucose through the glycolytic and hexose-monophosphate shunt pathways. Accordingly, lactate, which is the end product of these metabolic pathways, progressively accumulates during blood storage. As lactate increases, pH falls, inhibiting further glycolytic activity and decreasing adenosine triphosphate (ATP) and 2,3-DPG. As intraerythrocytic ATP concentrations decrease, membrane lipid is altered and sodium/potassium ATPase-dependent ion pumps are inhibited. This process results in rigid, spherocytic red cells; some have increased osmotic fragility and undergo spontaneous lysis, and some lyse in vivo. This altered RBC deformability may alter their capacity to pass through the capillary bed.

2,3-DPG is an important determinant of oxygen affinity and delivery. During storage, 2,3-DPG falls, and the oxygen-hemoglobin dissociation curve shifts leftward. This shift reflects an increase in the oxygen affinity of hemoglobin, which results in poor oxygen offloading unless tissue oxygen tension is lower than normal.

Additional biochemical changes are associated with the storage lesion. They result from the utilization of glucose and its metabolism to lactic acid and other organic acids, production of ammonia, and release of lactic dehydrogenase, potassium, and

plasma hemoglobin.

4. The approximate shelf life of a unit of packed red blood cells (PRBCs) preserved with citrate, phosphate, dextrose, and adenosine (CPDA-1) is approximately which of the following?

   A. 10 days

   B. 21 days

   C. 42 days

   D. 60 days

   Preferred response: C

Rationale

Advances in the development of anticoagulant-preservative solutions have focused on the use of nutrient cocktails designed to maintain 2,3-DPG and ATP, stabilize the RBC membrane, and maintain the 75% posttransfusion viability standard. CPDA-1 preserves RBCs for 35 days. New solutions permit 42-day storage. Also, because extra fluid is added to the newer nutrient solutions, these units have lower hematocrits and more rapid flow characteristics compared with RBCs stored in CPDA-1.

5. The average hematocrit of one unit of packed red blood cells (PRBCs) before and after the addition of preservative solutions is approximately which of the following?

   A. 45% and 30%

   B. 55% and 45%

   C. 65% and 45%

   D. 75% and 55%

   Preferred response: D

Rationale

PRBCs are prepared from whole blood after centrifugation or sedimentation. PRBCs collected in CPDA-1 anticoagulant have a volume of approximately 250 mL with a hematocrit of 70% to 80%. When PRBCs are supplemented with additive preservative solutions, the volume of the PRBC unit is increased to approximately 350 mL, and the hematocrit is reduced to 50% to 60%.

6. Which of the following has a 24-hour expiration after collection and storage?

   A. Frozen cryoprecipitate

   B. Platelet concentrate

   C. Washed RBCs

   D. Whole blood

   Preferred response: C

Rationale

Leukocyte-reduced packed red blood cells (PRBCs) may be prepared by a number of

different techniques. The average total leukocyte content in one unit of PRBCs is 2 to 5×10^9. Leukocyte reduction by modern filtration technology reduces the leukocyte content of RBCs by a factor of 10^3 to 10^4 and is often performed immediately after collection and prior to refrigerated storage. Deglycerolization requires defrosting and washing with automated cell washers. Washing reduces 70% to 90% of leukocytes, plasma, platelets, anticoagulant, and microaggregates. Deglycerolization requires defrosting and washing with automated cell washers. Cryopreserved and deglycerolized RBCs are reduced in leukocyte content by approximately 100-fold. Washed RBCs and deglycerolized cells have the disadvantage of 24-hour expiration once they have been manipulated by washing.

Frozen cryoprecipitate has an expiration period of 12 months. The shelf lives of whole blood, PRBC preserved with CPDA-1, and platelet concentrate are 21 to 35 days, 35 days, and 5 days, respectively.

7. Cryoprecipitate contains which coagulation factors?
   A. Factor V and factor VII
   B. Factor VIII and fibrinogen
   C. Factor VII and fibrinogen
   D. Factor VII and factor VIII
   Preferred response: B

Rationale

Cryoprecipitate antihemophilic factor is the cold-insoluble portion of plasma remaining after fresh frozen plasma (FFP) has been thawed between 1°C and 6°C and refrozen. Each bag of 10 to 15 mL contains 80 units of factor VIII and at least 150 mg of fibrinogen. Cryoprecipitate also contains factor VIII/von Willebrand factor and fibronectin, an opsonic protein that aids in phagocytosis.

8. Which of the following disorders is best treated with fresh frozen plasma (FFP)?
   A. Afibrinogenemia
   B. von Willebrand disease
   C. Factor IX deficiency
   D. Hereditary angioedema
   Preferred response: D

Rationale

FFP is indicated for plasma coagulation deficiencies when no alternative product is available. Examples include the rare single congenital deficiencies of factors II, V, VII, X, XI, and XIII. FFP is most commonly used to treat multiple coagulation deficiencies, such as in patients with liver disease, fat-soluble vitamin K deficiency related to malabsorption, biliary disease, or to address bleeding or urgent surgery in patients taking warfarin anticoagulants, or with disseminated intravascular coagulation. Other less common indications include replacement of C1 esterase inhibitor in patients with hereditary angioedema and use in patients with thrombotic thrombocytopenic purpura as a simple transfusion or as a part of a therapeutic plasma exchange.

Afibrinogenemia and fibronectin deficiency are best treated with cryoprecipitate. Factor VIII and IX deficiencies are most often treated with recombinant or plasma-derived factor concentrates.

Chapter 94: Hematology and Oncology Crises in the Intensive Care Unit

---

1. A 5-year-old boy who is previously healthy presents with a 2-week history of increased bruising. Complete blood cell count (CBC) reveals hemoglobin, 4.5 g/dL; hematocrit, 31%; white blood cell count (WBC), 9×10^9/L; and platelets, 6×10^9/L. He receives a bone marrow evaluation with no concern for malignancy, and therapy with intravenous immunoglobulin (IVIG) has started. At 12 hours into his hospital stay, he develops severe headache and persistent vomiting. What is the next step in caring for this patient?

   A. Check platelet count to assess the efficacy of IVIG.

   B. Obtain an emergent head computed tomography (CT).

   C. Start plasmapheresis emergently.

   D. Transfuse platelets to keep at about 20,000, given concern for intracranial hemorrhage.

   Preferred response: B

Rationale

The patient most probably has immune thrombocytopenic purpura (ITP) and is at risk for intracranial hemorrhage. A head CT will be the definitive test to determine the presence or absence of this complication. If intracranial hemorrhage is present, the therapeutic regimen should include IVIG, corticosteroids, and emergent splenectomy. Platelet consumption occurs in patients with ITP who receive platelet transfusions; therefore the platelet count in these patients does not increase with platelet transfusion. Platelet transfusions during life-threatening hemorrhage have been reported to decrease the rate of bleeding. In this case, the diagnosis of intracranial hemorrhage should be so established prior to platelet transfusion. A CT of the head CT must therefore occur prior to transfusion of platelets. Plasmapheresis can be performed as a last resort in patients with ongoing bleeding following maximal therapy for ITP (IVIG, corticosteroids, splenectomy, and platelet transfusions) but would not be performed until hemorrhage was shown to be present. The timeline for return to normal for platelet count in ITP patients is typically 48 hours and would not add information at this point in the care of the patient.

2. A 13-year-old girl presents with new onset of shortness of breath and difficulty sleeping. Physical examination reveals a patient with mild dyspnea and orthopnea at rest, with both inspiratory and expiratory wheezes, as well as cervical

lymphadenopathy. Chest radiograph reveals a large mediastinal mass. Chest computed tomography (CT) scan confirms the presence of a large mass with tracheal compression estimated at 50%. In order to begin therapy, tissue diagnosis is needed. What is the optimal method to obtain a tissue biopsy in this patient?

A. Obtain peripheral blood sample and proceed with empiric chemotherapy.

B. Perform emergent endotracheal intubation.

C. Perform magnetic resonance imaging (MRI) with sedation to determine the extent of the mass.

D. Perform tissue biopsy under local anesthesia.

Preferred response: D

Rationale

Patients with anterior mediastinal masses can experience serious complications during general anesthesia, usually due to extrinsic compression of the airway, obstruction of venous return, or obstruction to the output of the heart. The masses that are most likely to cause anesthetic problems in children are rapidly growing hematologic emergencies. Recommendations for the care of these patients include CT imaging, which is tolerated in most patients due to the short duration of the scan. MRI requires a long period of time and may not be tolerated. The patient described has signs and symptoms of respiratory compromise and would be at high risk for general anesthesia.

If possible, the best course of action would be to obtain a biopsy under local anesthetic in order to gain a tissue diagnosis prior to the initiation of therapy. General anesthesia and intubation should be avoided. Peripheral blood sample would possibly contribute to a diagnosis but may not be conclusive.

3. Which statement about anemia is true?

A. Oxygen consumption often becomes oxygen delivery dependent at hemoglobin levels of 8 g/dL.

B. Chronic anemia shifts the oxyhemoglobin curve to the right.

C. A decreasing hematocrit worsens venous return and decreases preload.

D. Massive transfusion of packed red blood cells is associated with an increase in coagulation factors.

Preferred response: B

Rationale

Chronic anemia increases the amount of 2,3-diphosphoglycerate inside the red blood cells and subsequently causes a right shift of the oxyhemoglobin dissociation curve. In bonding to partially deoxygenated hemoglobin, 2,3-diphosphoglycerate allosterically up-regulates the release of the remaining oxygen molecules bound to hemoglobin.

Under steady-state conditions, oxygen consumption remains constant and is independent of oxygen delivery until it falls below a critical level, which varies for each organ system. When the hemoglobin concentration decreases to approximately 5 g/dL or less, oxygen delivery and consumption may be altered. Below this level,

oxygen consumption becomes delivery dependent.

The body responds to acute, normovolemic anemia by increasing cardiac output through increases in stroke volume, heart rate, or both. As the hematocrit falls, blood viscosity diminishes, thus increasing venous return and augmenting preload.

If packed red blood cells or plasma-poor red blood cells are used to correct oxygen-carrying capacity during massive blood loss, deficits of coagulation factors develop earlier than during transfusion of whole blood. Hypofibrinogenemia generally develops first, followed by deficits in other clotting factors and later by thrombocytopenia.

4. Which of following should be used with caution (if at all) in the treatment of tumor lysis syndrome?

   A. Alkalinization

   B. Allopurinol

   C. Diuretics

   D. Urate oxidase

   Preferred response: C

Rationale

Alkalinization of the urine increases solubility of uric acid and limits precipitation of uric acid crystals in the renal tubule. Allopurinol, a xanthine analogue, competitively blocks the enzyme xanthine oxidase. It reduces the formation of uric acid but it cannot lower elevated uric acid levels that precede therapy. Urate oxidase (rasburicase), a recombinant proteolytic enzyme, cleaves uric acid to highly soluble allantoins. The use of urate oxidase has decreased the need for dialysis. Diuretic therapy might increase renal excretion of K^+ in the face of hyperkalemia, but dehydration may worsen electrolyte abnormalities by precipitating preexisting renal dysfunction. Hydration is a key concept to ensure adequate end-organ perfusion, especially of the renal vascular bed.

Chapter 95: Critical Illness Involving Children Undergoing Hematopoietic Cell Transplantation

---

1. A 12-year-old female presents 20 days after a marrow infusion for acute lymphoblastic leukemia (ALL). This is her first hematopoietic stem cell transplant. She is showing the first signs of engraftment with the beginnings of a fine papular rash possibly representing mild graft-versus-host disease and an increasing neutrophil count. She develops a fever and increased work of breathing with a new oxygen requirement of 6 liters/minute by simple facemask. Her chest x-ray shows bilateral diffuse infiltrates. A bronchoscopy is performed 24 hours later. All stains are negative for organisms, as are all cultures. What would be the next best step?

A. Start ganciclovir, as this most likely represents cytomegalovirus (CMV) pneumonitis.

B. Start steroids, as this likely represent periengraftment respiratory distress syndrome or idiopathic pneumonia syndrome, either of which could respond to steroids.

C. Start sulfamethoxazole-trimethoprim therapy, as this likely represents *Pneumocystis jirovecii* infection.

D. Obtain an open lung biopsy to get a clearer idea of the etiology of lung disease before beginning therapy.

Preferred response: B

Rationale

The timing of the patient's respiratory distress in the periengraftment period fits well with periengraftment respiratory distress syndrome. This syndrome may respond well to steroids. Another possibility would be idiopathic pneumonitis, as the bronchoscopy results did not show any evidence of infection. Steroids may be beneficial in this circumstance as well. CMV pneumonitis is an unlikely diagnosis with current surveillance and prophylactic strategies. Although a fungal pneumonia is possible, given the early timing of the illness and bronchoscopy results without evidence of an organism, this is less likely. Pneumocystis infections are also uncommon given current preventative strategies as well as bronchoscopy results without evidence of infection. An open lung biopsy could eventually be indicated if the patient does not respond to steroids and the diagnosis remains in question. However, at this point the risk of the procedure outweighs the possible benefit.

2. A 3-year-old male is now on day 9 after an allogeneic matched sibling hematopoietic cell transplant for relapsed leukemia. He was doing well until 2 days ago when he developed right upper quadrant abdominal pain, jaundice, increased platelet transfusion requirements, and fluid retention. His coagulation profile and liver function tests are normal except for a bilirubin of 2.5 mg/dL. His conditioning regimen consisted of cyclophosphamide and busulfan. What disease process are you most worried about, and what should you do next?

A. Cytomegalovirus (CMV) hepatitis—obtain quantitative CMV polymerase chain reaction (PCR) to confirm your diagnosis.

B. Graft-versus-host disease (GVHD) of the liver *Pneumocystis jirovecii*—begin pulse dose methylprednisolone at 2 mg/kg/day divided every 12 hours.

C. Thrombotic microangiopathy—obtain peripheral blood smear to look for schistocytes.

D. Veno-occlusive disease (VOD) of the liver—obtain a liver ultrasound with Doppler imaging looking for reversal of portal venous flow.

Preferred response: B

Rationale

VOD occurs in the first 100 days after transplant and typically occurs within the first few weeks. This patient has several risk factors for VOD—age less than 6 years, a

conditioning regimen with busulfan and cyclophosphamide, and a potential risk for iron overload given his diagnosis of relapsed leukemia and the likelihood of requiring numerous packed red blood cell (PRBC) transfusions in the past. A liver ultrasound is noninvasive and relatively easy to obtain. Although a reversal of portal venous flow is not necessary for the diagnosis of VOD and is a late finding of the disease, it is specific and if seen would confirm the diagnosis. A late finding of reversal of portal venous flow would warrant more aggressive treatment such as the use of defibrotide.

CMV hepatitis is a possibility, but because of the current strategies for CMV surveillance and prevention, this is less likely. It would not be wrong to test for CMV, but it should not be your highest priority. GVHD of the liver and VOD are sometimes difficult to differentiate, as signs and symptoms often overlap. In this particular case, the patient has risk factors for VOD but is at a lower risk for GVHD given the donor was a matched sibling. Also, GVHD of the liver often presents with transaminitis, whereas patients with VOD often have normal liver enzymes. Thrombotic microangiopathy can cause thrombocytopenia and hyperbilirubinemia from hemolysis. However, thrombotic microangiopathy should not cause as much fluid retention and abdominal pain. Sepsis should always be on the differential for any patient who appears ill in the early transplant period, and it would not necessarily be wrong to start antibiotics. However, in the absence of fever and the clinical picture being consistent with VOD, VOD is a more likely diagnosis.

3. A child who has had a hematopoietic stem cell transplantation (HSCT) with neutropenia and graft-versus-host disease (GVHD) demonstrates fever, cough, dyspnea, and hemoptysis 2 weeks following construction on the ward where he is being treated. Which of the following organisms should be particularly suspect for the cause of pneumonitis?

   A. *Aspergillus*

   B. *Candida*

   C. Cytomegalovirus

   D. *Staphylococcus*

   Preferred response: A

Rationale

Aspergillus spores are routinely inhaled, and in an immunocompromised patient or one who has undergone an HSCT, these spores can cause invasive infections. Neutropenia and GVHD with immunosuppressive treatment are risk factors for invasive infections resulting from *Aspergillus* spores. Outbreaks of *Aspergillus* can occur in areas of construction or in areas with contaminated ventilation. Invasive aspergillosis occurs most commonly in the lungs. The characteristic radiographic appearance is a cavitary lesion, but nodular infiltrates and bronchopneumonia also are seen. Diagnostic bronchoalveolar lavage should be performed initially.

4. Tremor, headaches, mental status changes, and then onset of seizures and cortical blindness develop in a child who has had a hematopoietic stem cell transplantation (HSCT) and who has had no previous neurologic problems. Which of the following drugs utilized in his treatment regimen would be most likely

associated with this constellation of new symptoms?

A. Amphotericin

B. Cyclosporin A

C. Defibrotide

D. Methylprednisolone

Preferred response: A

Rationale

Neurotoxicity from cyclosporin A or tacrolimus, which is used for graft-versus-host disease (GVHD) prophylaxis or treatment, can include tremor, seizures, headaches, cortical blindness, neuropathy, or mental status changes. Frequently these symptoms are observed with levels above the therapeutic range, but this is not always the case. These effects usually are reversible with elimination of the drug. These medications also may be associated with the posterior reversible leukoencephalopathy syndrome.

5. Which of the following cells is most likely responsible for transfusion-acquired (TA) graft-versus-host disease (GVHD)?

A. Basophil

B. Lymphocyte

C. Macrophage

D. Neutrophil

Preferred response: B

Rationale

TA GVHD occurs when an immunosuppressed or immunodeficient transfusion recipient receives immunologically competent donor lymphocytes. The transfused histoincompatible T lymphocytes proliferate and engraft in the immunocompromised host, who is incapable of rejecting foreign cells. This situation is most likely to occur when family members serve as directed donors, although TA GVHD from unrelated donors has been reported.

Clinical symptoms of TA GVHD usually begin 4 to 30 days after transfusion and include fever, erythematous rash, anorexia, nausea, vomiting, and profuse watery diarrhea. The erythematous rash may progress to bullae and desquamation. Liver dysfunction, from simple liver enzyme elevation to fulminant hepatic coma, can occur. Severe cytopenias may develop and help differentiate TA GVHD from that occurring in bone marrow transplant recipients. TA GVHD is fatal in 90% of reported pediatric cases.

6. Which method best reduces the occurrence of transfusion-acquired (TA) graft-versus-host disease (GVHD) in immunocompromised patients who are receiving blood transfusions?

A. Deglycerolization

B. Filtration

C. Freezing and washing

D. Irradiation

Preferred response: D

Rationale

Because the lymphocyte is the most likely initiator of TA GVHD, the disease can be prevented by reducing the number of lymphocytes or by rendering them mitotically inactive. Because TA GVHD has been reported after leukocyte reduction by filtration, γ irradiation currently is the only adequate method for preventing TA GVHD.

7. Fungal involvement of the liver in patients with hematopoietic stem cell transplantation (HSCT) is most often due to which of the following?

   A. *Aspergillus*

   B. *Blastomyces*

   C. *Candida* species

   D. *Cryptococcus*

   Preferred response: C

Rationale

Hepatic complications of HSCT include infectious hepatitides (viral, fungal, bacterial), cholestasis, drug toxicity, veno-occlusive disease, and GVHD. Fungal involvement of the liver is often seen in conjunction with widespread dissemination. Granulomas, abscesses, cysts, fungus in biliary ducts, or infarcts from vascular occlusion may occur. Typically, *Candida* species are seen; however, any fungal pathogen can occur. Ultrasound or computed tomography scan may help identify a lesion. Ultrasound-guided fine-needle aspiration can confirm the diagnosis. Bacterial infections of the liver occur less commonly but present similarly.

8. On day 45 after undergoing a hematopoietic stem cell transplantation (HSCT), a 10-year-old child experiences an erythematous rash starting on his palms and soles and spreading to his chest and abdomen. Fever and diarrhea also develop. It is most likely that which of the following abnormalities also would be present in this condition?

   A. Elevation of blood urea nitrogen and creatinine

   B. Elevated bilirubin or alkaline phosphatase

   C. Eosinophilia

   D. Leukopenia

   Preferred response: B

Rationale

This patient has manifestations of acute GVHD. The skin, gastrointestinal tract, and liver are the most common systems involved in acute GVHD. The cutaneous presentation is typically an erythematous maculopapular rash, although a wide variety of skin findings are possible. Diffuse bullous lesions with skin sloughing are the most severe manifestation of cutaneous GVHD. Acute gastrointestinal GVHD is characterized by diarrhea that is often bloody and may contain tissue. Hepatic acute

GVHD typically presents with a cholestatic pattern of elevated bilirubin and alkaline phosphatase. Isolated transaminase elevation is uncommon. Less common presentations of acute GVHD are oral inflammation with possible ulceration and ocular inflammation. Acute GVHD is graded according to severity of the systems involved (Table Q95.8).

9. What is the first line of treatment for the condition described in question 8?

   A. Corticosteroids

   B. Cyclophosphamide

   C. Cyclosporin A

   D. Tacrolimus

TABLE Q95.8

Consensus Criteria for Clinical Staging and Grading of Acute Graft-Versus-Host Disease

	Skin	Liver	Gut
Stage			
1	Rash* <25% or persistent nausea†	Bilirubin 2-3 mg/dL‡	Diarrhea >500 mL/day§
2	Rash* 25%-50%	Bilirubin 3-6 mg/dL	Diarrhea >1000 mL/day
3	Rash >50%	Bilirubin 6-15 mg/dL	Diarrhea >1500 mL/day
4	Generalized erythroderma with bullae	Bilirubin >15 mg/dL	Severe abdominal pain with or without ileus
Grade‖			
I	Stage 1-2	None	None
II	Stage 3 or	Stage 1 or	Stage 1
III	—	Stage 2-3 or	Stage 2-4
IV	Stage 4 or	Stage 4 or	Stage 4¶

*Use "rule of nines" or burn chart to determine extent of rash.

†Persistent nausea with histologic evidence of graft-versus-host disease in the stomach or duodenum.

‡Range given as total bilirubin. Downgrade one stage if an additional cause of elevated bilirubin can be documented.

§Volume of diarrhea applies to adults. For pediatric patients, the volume of diarrhea should be based on body surface area. Downgrade one stage if an additional cause of diarrhea has been documented.

‖Criteria for grading given as degree of organ involvement required to confer that grade.

¶Grade IV may include lesser organ involvement with Karnofsky performance status <50%, so patients with stage 4 gut GVHD usually are grade IV.

From Przepiorka D, Weisdorf D, Martin P, et al. 1994 consensus conference on acute GVHD grading. Bone Marrow Transplant. 1995;15:825-828.

Preferred response: A

Rationale

GVHD is the most common complication of allogeneic HSCT. GVHD develops when donor T lymphocytes respond to proteins on recipient cells. Activated donor T lymphocytes, monocytes, and macrophages trigger a self-propagating cycle of cytokine production and inflammation. GVHD can be either acute or chronic. Classic acute GVHD occurs at any point after engraftment until approximately 100 days after transplantation. Late-onset acute GVHD clinically resembles acute GVHD but occurs more than 100 days after transplantation. Prevention of GVHD is best accomplished by human leukocyte antigen matching of donor and recipient. Despite

this step, however, acute GVHD still occurs in 30% to 70% of human leukocyte antigen–genotypically matched recipients. Most institutions use cyclosporine or tacrolimus (FK506) either alone or in combination with short-course methotrexate or steroids as prophylaxis against GVHD. T-cell depletion of donor stem cells by various methods can reduce the risk of GVHD but is associated with higher rates of graft failure and a risk of posttransplantation lymphoproliferative disorder.

Corticosteroids are the mainstay of treatment for GVHD. Other upfront treatments that specifically target affected systems are oral dexamethasone and tacrolimus rinses and corticosteroid or tacrolimus topical therapies. Many second-line agents and treatment strategies are available for GVHD that is refractory to steroids, but none is considered standard. The choice of second-line therapy depends on the individual clinical situation.

10. To prevent the condition described in question 8, you had started prophylaxis immediately after the transplant occurred. The child experienced gingival hyperplasia, hirsutism, hypomagnesemia, seizures, and hypertension. Which drug is likely responsible for these adverse effects?

A. Corticosteroids

B. Cyclophosphamide

C. Cyclosporin A

D. Mycophenolate

Preferred response: C

Rationale

Neurotoxicity from cyclosporin A or tacrolimus, which is used for GVHD prophylaxis or treatment, can include tremor, seizures, headaches, cortical blindness, neuropathy, or mental status changes. These effects usually are reversible with elimination of the drug. As many as 5% to 6% of patients who undergo HSCT and take cyclosporin A may experience seizures.

Cyclosporin A, tacrolimus, and chemotherapeutics also may cause renal wasting of magnesium resulting in hypomagnesemia and lowering of the seizure threshold. In addition to hypomagnesemia, other metabolic abnormalities may occur in this setting that contribute to seizures. Moreover, metabolic derangements resulting in encephalopathy have been considered the most common neurologic complication following hematopoietic stem cell transplantation (HSCT), with an incidence estimated to be as high as 37%. A more recent pediatric analysis suggests that metabolic derangements remain a significant cause of encephalopathy following HSCT, but with a much lower incidence (14%) than that revealed in the earlier study. Hypoxia, ischemia, hepatic failure, electrolyte imbalance, and renal failure all have been found to be etiologies of these metabolic derangements resulting in encephalopathy.

Glucocorticoids used for immunosuppression can be associated with mood swings, dysphoria, agitation, and frank psychosis. Patients may experience steroid-induced myopathy that results in symmetric weakness of proximal muscles. Other adverse effects of these drugs are listed in Table Q95.10.

11. Which of the following anticonvulsants would be *least* likely to interfere with

calcineurin metabolism?

A. Carbamazepine

B. Phenobarbital

C. Phenytoin

D. Valproic acid

TABLE Q95.10

Adverse Effects of Immunosuppressants

Agent	Adverse Effects
Tacrolimus	Hypertension, headache, infection, seizures, hyperglycemia, insulin resistance/diabetes, renal failure, posttransplant lymphoproliferative disorder (PTLD), cardiomyopathy
Cyclosporine	Hypertension, infection, seizures, hyperglycemia, renal failure, hirsutism, gingival hyperplasia, PTLD
Sirolimus	Hypercholesterolemia, infection, edema, PTLD
Corticosteroids	Hypertension, increased appetite, Cushing syndrome, acne, gastritis, poor wound healing, osteoporosis, poor linear growth
Mycophenolate	Intestinal hypermotility, cramping, diarrhea, infection, leukopenia, thrombocytopenia

Preferred response: D

Rationale

Phenytoin, phenobarbital, and carbamazepine, which may be used to treat seizures, can alter cytochrome P-450 and interfere with cyclosporin A or tacrolimus levels. Valproic acid may be a better alternative in this situation.

Chapter 96: Gastrointestinal Structure and Function

1. Which of the following statements regarding digestion and nutrition is true?

   A. During digestion, the enterocyte receives a significant majority of its nutrition through the vascular supply.

   B. Healthy infants up to 6 months of age absorb 95% of the dietary fat.

   C. In the premature infant and neonate, the small intestine is capable of absorbing intact milk proteins by pinocytosis.

   D. Most of the enzymatic degradation of dietary lipids to fatty acids and monoglyceride requires an acidic environment.

   Preferred response: C

Rationale

During periods of fasting, the enterocyte derives the majority of its nourishment from the mesenteric arterial vascular supply, whereas during digestion, the enterocyte derives a significant part of its nutrient requirements from the luminal contents. Experience with mucosal recovery and adaptation after injury reveals that an enteral route of nutrition permits optimal recovery. In the premature infant and neonate, the small intestine is capable of absorbing intact milk proteins by

pinocytosis. These proteins may include secretory immunoglobulins from breast milk as well as food antigens. Peptidase inhibitors have been demonstrated in colostrum and breast milk, partially explaining the failure of normal digestive mechanisms to degrade some of these complex dietary proteins. Both antibodies and antigens ingested with maternal milk create an important part of the immune repertory developed during early infancy. Although the exact time of “closure” of the intestinal mucosa to the uptake of macromolecules has not been defined in human infants, other mammals demonstrate marked intestinal impermeability to foreign proteins by the time they are weaned from breast-feeding.

In healthy adults, digestion and absorption of fat is complete with only 5% to 7% of ingested fat escaping absorption. Under normal physiologic conditions, healthy infants up to age 9 to 12 months fail to absorb 15% to 35% of dietary fat. Digestion and absorption of dietary fat is generally completed by the middle third of the jejunum; however, the presence of dietary fiber may reduce the rate and extent of absorption. Loss of dietary fat places children at significant risk for calorie and fat-soluble vitamin malnutrition.

Most of the enzymatic degradation of dietary lipids to fatty acids and monoglyceride occurs by the action of pancreatic lipase and co-lipase, and it requires an alkaline environment (pH 6 to 8). This underscores the importance of secretion of bicarbonate by the pancreas and biliary tract in order to neutralize gastric acid.

2. Which of the following substances synthesized in the liver is a useful marker for protein-losing enteropathy?

   A. α_1-Antitrypsin

   B. Fibrinogen

   C. Prealbumin

   D. Transthyretin

   Preferred response: A

Rationale

α_1-Antitrypsin is an important antiprotease with regulatory activity for elastase and other plasma proteases. α_1-Antitrypsin is important for regulating elastase-induced tissue injury in certain lung diseases, and its absence leads to uncontrolled proteolytic activity in the lung. Because α_1-antitrypsin is an endogenous protein that is relatively resistant to hydrolysis by enteric bacteria, it is a useful marker of protein-losing enteropathy.

Prealbumin, also known as transthyretin, is a visceral protein with a short half-life of ~1.9 days. Because hepatic synthesis is exquisitely sensitive to both the adequacy and levels of protein and energy intakes, it may be used as a nutritional marker and for monitoring the short-term response to nutritional intervention.

Hepatic synthesis of transferrin facilitates iron transport in the plasma by binding two molecules of iron. Ferritin is the primary storage molecule of iron, with each molecule storing up to 4500 atoms of iron. Many coagulation factors are synthesized in the liver. They include plasminogen, fibrinogen, and factors II, V, VII, IX, X, XI, XII, and XIII. Factors II, VII, IX, and X are the so-called vitamin K–dependent factors that require vitamin K for synthesis and secretion in active form. In addition, the

anticlotting proteins antithrombin III, protein C, and protein S are synthesized largely in the liver.

3. Proteins are broken down into oligopeptides in the lumen by digestive enzymes but are most efficiently absorbed as which of the following?

   A. Intact protein via pinocytosis

   B. Oligopeptides and dipeptides

   C. Peptides encased in chylomicrons

   D. Single amino acids

   Preferred response: B

Rationale

Because of brush border transport mechanisms that are typically adenosine triphosphate dependent and often coupled to Na^+ and H^+ transport, dipeptides and tripeptides are most efficiently absorbed.

4. What leads to portal hypertension?

   A. Advanced hepatic cirrhosis only

   B. Impaired drainage of portal blood

   C. Presence of esophageal varices

   D. Splenomegaly

   Preferred response: B

Rationale

Portal hypertension is seen in any situation that impairs egress of portal venous blood via the normal circulation through the liver. The normal transhepatic portal venous pressure gradient is <5 mm Hg. Thus any process that increases back pressure or hepatic vascular resistance will lead to diversion of blood flow via collateral circulation involving the esophageal and splenic venous circulation.

Chapter 97: Disorders and Diseases of the Gastrointestinal Tract and Liver

---

1. Which of the following represents a correct treatment approach for pancreatitis?

   A. Antibiotics are a mainstay of treatment for all cases.

   B. Early, enteral feeding is the preferred route of nutrition.

   C. Intravenous glucagon is effective therapy.

   D. Intravenous somatostatin should be provided for 1 to 2 days.

   Preferred response: B

Rationale

Historically, it was thought that “resting” the pancreas and making patients NPO until they improved clinically was the correct treatment for pancreatitis; however, patients who are fed enterally were found to have reduced morbidity and mortality as compared to those who were fed parenterally.

2. Which of the following is true of abdominal compartment syndrome?
   A. Bladder pressure should be measured while the patient's head of bed is at at least a 30-degree angle.
   B. Chest wall compliance is increased.
   C. Diaphragmatic excursion is increased.
   D. The sustained urinary bladder pressure is greater than 20 mm of Hg.
   Preferred response: D

Rationale

Bladder pressure should be measured with a patient flat and muscle relaxed if feasible. Bladder pressures greater than 20 mm Hg are concerning for abdominal compartment syndrome. Diaphragmatic excursion and chest wall compliance are both decreased.

3. For patients in an intensive care setting, which of the following best documents gastroesophageal reflux (GER)?
   A. Colorization of formula with blue dye
   B. Esophageal impedance monitoring
   C. Esophageal pH monitoring
   D. Radionuclide formula scanning
   Preferred response: B

Rationale

Esophageal impedance monitoring is the preferred means of measuring GER in patients who are receiving acid suppression or in whom alkaline reflux is suspected. The intraesophageal impedance device measures total opposition to current flow between two electrodes and expresses the value in ohms. Because air and fluid have different conductivities, the contents of the esophagus can be differentiated at any point in time. Thus when the esophagus is devoid of fluid, a baseline impedance is measured. When a bolus of fluid enters the esophagus from refluxed material or from a swallowed bolus, the impedance changes. These changes in intraluminal impedance thus permit the continuous monitoring of pH neutral or alkaline reflux episodes.

Esophageal pH monitoring involves continuously recording the esophageal pH for 24 hours. The duration of esophageal acidification, defined as decreases in pH less than 4, is quantified. Additional variables, including the quantity of reflux in the 2 hours after a feeding and during fasting, are determined. Detection of alkaline reflux episodes, which commonly occur in the postprandial period when food buffers gastric acid, is not possible with this technique. This technique is unreliable

for children who have been maintained with histamine 2 (H_2) antagonists or proton pump inhibitors. For reliable pH monitoring of such children, proton pump inhibitors must have been discontinued for at least 72 hours and H_2 antagonists for at least 48 hours. Critical care physicians may not have the luxury of stopping these agents temporarily in critically ill patients who are at risk for stress ulceration of the gastrointestinal tract.

A coloring agent such as blue dye number one or methylene blue has been added to formula in the past as a simple way of documenting aspiration in patients receiving gavage or gastrostomy feedings. The rationale for this strategy was that quantities sufficient to tint formula should be readily apparent when suctioned from the lungs. This technique is notoriously inaccurate when compared with scintiscanning of the lungs after administration of a radiolabeled meal or with the discovery of lipid-laden macrophages after bronchoalveolar lavage.

GER and the rate of gastric emptying can be measured with liquid-phase gastroesophageal scintigraphy, which can be used to measure technetium 99-sulfur colloid, which is mixed with formula or another enterally administered liquid. When a scan is performed above and below the diaphragm in 30- to 60-second windows during the first postprandial hour after isotope administration, the number of reflux episodes, the height of the reflux column, and the rate of gastric emptying are quantitated. A 4- to 6-hour delayed scan of the lungs determines whether pulmonary aspiration of that meal has occurred.

For an ambulatory child capable of undergoing an endoscopy, a small pH transducer capsule can be deployed, attached to the esophagus, and left in place to monitor esophageal acidification for up to 48 hours with an external sensor before being naturally sloughed. The advantage of using this device is that nasoesophageal intubation need not be performed, thereby creating a more natural environment. For a critically ill, intubated patient, this device is impractical to place and offers no advantage over traditional reflux monitoring.

4. Abdominal compartment syndrome is best diagnosed by which pressure measurement?

A. Central venous pressure

B. Intragastric pressure

C. Intrarectal pressure

D. Urinary bladder pressure

Preferred answer: D

Rationale

The standard method for measuring intraabdominal pressure is through the assessment of bladder pressure. A three-way stopcock is placed between the catheter and pressure tubing. The bladder is emptied and sterile isotonic saline solution is injected in the distal stopcock and into the bladder to allow for a continuous fluid column. There is some variability in the amount of fluid administered based on tubing and patient size. The pressure transducer is zeroed at the level of the midaxillary line and the pressure is measured at end expiration while the patient is supine.

5. A 3-year-old child who accidentally ingested a household product containing lye is admitted to the pediatric intensive care unit. She presents with mild stridor, mouth burns, and increased salivation. Which of the following statements regarding this patient is correct?

   A. An endoscopy should not be performed in this patient because of an increased risk of perforation.

   B. Steroids have not been shown to prevent sequelae in these cases.

   C. The chance of esophageal injury in this patient is minor.

   D. This child requires immediate endotracheal intubation.

   Preferred response: B

Rationale

Deep esophageal burns are more common after alkali ingestion. Alkalis produce rapid liquefaction of esophageal tissue, and burns can range from first to third degree in depth. An intense inflammatory infiltrate develops, and blood vessels thrombose to produce ischemic necrosis. Perforation may occur within hours or days. Strictures can occur weeks to years after ingestion. Esophageal burns occur infrequently after acid ingestion, but gastric or duodenal erosions have been reported.

Symptoms that predominate are chest pain and the inability to swallow secretions. Children with upper airway damage often exhibit stridor. When mouth burns are present, the chances of esophageal injury are 75%.

Treatment of severe stridor should be directed toward establishing an airway, and emergency tracheostomy should be contemplated. Upper endoscopy within 24 hours is advisable. If burns are minor, no further therapy is necessary, and patients are at low risk of sequelae. However, third-degree burns require ongoing intensive care.

The role of antibiotics and steroids remains controversial. Although steroids reduce tissue damage when given before an experimental injury, recent double-blind clinical trials show no efficacy of steroids in preventing sequelae. When third-degree burns are endoscopically evident, a nasogastric tube should be positioned with endoscopic guidance. This tube will enable early feeding and serve as a guide for future dilations if they become necessary. Some surgeons have advocated early placement of gastrostomies and esophageal stents in patients with third-degree burns.

6. Which of the following types of foreign body lodged in a child's esophagus warrants immediate removal (less than 4 hours after ingestion)?

   A. All foreign bodies

   B. Button batteries

   C. Metallic toys

   D. Wooden toys

   Preferred response: B

Rationale

Children can swallow a variety of metallic, wooden, or plastic foreign bodies in a

myriad of shapes and sizes. All that are lodged in the esophagus require urgent removal (within 24 hours). Even more urgent endoscopic retrieval is required for button batteries or pennies minted after 1983 that are lodged in the esophagus because both are caustic to esophageal mucosa and may cause damage within 1 to 4 hours. The preponderance of evidence suggests that once a battery has escaped the esophagus, complications from an unretrieved battery are rare.

Similarly, pennies minted after 1983 are predominantly zinc based and can be nearly as caustic within the esophagus as button batteries. No published epidemiologic studies are available on which to base the approach to zinc-based pennies within the stomach or small intestine.

7. Which of the following is a frequent associated finding in patients with a gastric ulcer?

   A. Delayed gastric emptying

   B. Gastroesophageal reflux

   C. Hyperchlorhydria

   D. Infection with *Helicobacter pylori*

   Preferred response: A

Rationale

Most patients with gastric ulcers are hypochlorhydric rather than hyperchlorhydric because exposure to detergents or toxins such as nonsteroidal antiinflammatory drugs, pepsin, bile salts, or ethanol erodes the gastric barrier to back diffusion. A second consistent finding in patients with gastric ulcers is delayed gastric emptying, which may be an epiphenomenon or central to the pathogenesis of ulcers. The association between *Helicobacter pylori* infection and both chronic gastritis and duodenal ulcer is well established, but the role of *H. pylori* in the pathogenesis of gastric ulceration remains somewhat speculative.

8. A 10-year-old child with hyperlipidemia type I presents with severe left upper quadrant abdominal pain radiating to the back. Serum lipase and amylase are significantly elevated. What abnormality is commonly encountered in this case scenario?

   A. Hyperkalemia

   B. Hypermagnesemia

   C. Hypocalcemia

   D. Hypophosphatemia

   Preferred response: C

Rationale

The clinical hallmark of acute pancreatitis is severe, boring epigastric or left upper quadrant pain that radiates through to the back. Serum amylase and lipase levels are greatly elevated, and radiographic imaging studies reveal pancreatic enlargement, sonolucency, or irregularity of the margin. Ultrasonography is a satisfactory screening technique, but computed tomography scanning should be used when the course is severe. If computed tomography scanning is performed with a dynamic,

contrast-enhanced technique, interstitial pancreatitis can be differentiated from the more ominous necrotic pancreatitis, which often requires surgical debridement.

Because serum lipase is almost exclusively pancreatic in origin and amylase comes from a number of organs, the serum lipase concentration may be a better indicator of pancreatitis. Use of both measures to follow the course of pancreatitis is preferable to using either one alone.

Several nonspecific laboratory derangements such as anemia, hypoglycemia, hypocalcemia, and hypoproteinemia may occur. Intensive support may be required for severe, acute attacks. Severe hemorrhagic necrosis of the pancreas carries a poor prognosis. Extraordinarily large third-space fluid and electrolyte losses must be replaced. If significant hyperglycemia occurs, insulin must be given. Calcium infusions also may be necessary.

9. Which of the following agents contributes to a decrease in ammonia production in patients with encephalopathy due to acute liver failure?

A. Cathartic agents

B. Hydroxyurea

C. Lactulose

D. Neomycin

Preferred response: D

Rationale

Encephalopathy is generally treated by the administration of ammonia-lowering agents. Neomycin, by qualitatively altering gut flora, reduces the enteral contribution to the ammonia load. Byproducts of the fermentation of lactulose by colonic bacteria reduce luminal pH to trap ammonia as ammonium for excretion in stool. Cathartic agents can speed transit of protein through the gastrointestinal tract. Dietary protein can be limited and the quality altered to include less aromatic amino acid and more branched-chain amino acid. Progressive hepatic encephalopathy culminates in coma. When patients have entered a coma, central nervous system (CNS) resuscitation becomes necessary. Patients should undergo elective endotracheal intubation, and they should be hyperventilated. Administration of narcotics and benzodiazepines should be avoided. Benzodiazepine antagonists provide temporary improvement in consciousness among patients with hepatic encephalopathy. Beyond CNS metabolic derangements, cytotoxic cerebral edema often complicates hepatic failure. Placement of an intracranial monitoring device should be contemplated; the risk of instrumentation in patients with coagulopathy should be weighed against the benefit of continuous CNS pressure monitoring. Plasmapheresis or plasma exchange will remove circulating mediators and toxins from patients with liver failure. This temporary effect may be due to removal of neuroinhibitory factors.

Chapter 98: Applications of Gastrointestinal Pharmacology

1. Stress ulcer prophylaxis is given to children in the pediatric intensive care unit to avoid which of the following outcomes?

   A. All forms of stress-related mucosal damage to the stomach and small intestine

   B. Coffee-ground emesis

   C. Esophageal irritation from reflux of gastric contents into the esophagus

   D. Hypotension or need for red blood cell transfusion

   Preferred response: D

Rationale

The goal of giving stress ulcer prophylaxis in any form is to decrease the risk of hemodynamically significant gastrointestinal bleeding rather than protect against any form of injury to the stomach or intestine that is related to critical illness. The same medications given for stress ulcer prophylaxis, such as ranitidine or a proton pump inhibitor, can be given for different indications. Other common indications in the PICU include mild bleeding from the stomach or small intestine as might be the cause in a patient with coffee-ground emesis or heme-positive stool. It is also common for patients to receive these medications for esophageal irritation from gastroesophageal reflux disease, often as a home regimen. When prescribing a medication in the PICU, it is important to recognize what effect one is hoping to see or what complication one is hoping to avoid. In the case of stress ulcer prophylaxis for critically ill children, one is hoping to avoid hemorrhage from the stomach or small intestine that is hemodynamically significant, which for study purposes has been defined as causing hypotension or requiring blood transfusion.

2. Antibiotic-associated diarrhea is common in the pediatric intensive care unit population. Which of the following statements best describes the relationship of probiotic therapy for antibiotic-associated diarrhea?

   A. In general, probiotic therapy prevents antibiotic-associated diarrhea.

   B. There is a superior bacterial probiotic formulation that is recommended to prevent antibiotic-associated diarrhea.

   C. There are many yeast probiotic formulations, in addition to multiple bacterial probiotic formulations.

   D. There is no concern for translocation of probiotic bacteria from the gut into the bloodstream with the potential for sepsis.

   Preferred response: A

Rationale

Various studies of probiotics for antibiotic-associated diarrhea are challenging to compare because they examine different microorganisms at different doses. Despite the heterogeneity of studies regarding probiotics, a meta-analysis by the Cochrane group supports the conclusion that probiotic therapy prevents antibiotic-associated diarrhea. There is no clear superior probiotic formulation to treat antibiotic-associated diarrhea. There is only one yeast probiotic formulation, whereas there are many bacteria utilized for probiotic therapy. Probiotic administration may not be an entirely benign intervention for antibiotic-associated diarrhea as there is a potential

for bacteremia with translocation across the gut, especially in patients at risk of impaired intestinal wall integrity such as premature infants and patients with oncologic diagnoses and mucositis.

3. Which of the following medications used for acute or delayed chemotherapy-induced nausea and vomiting (CINV) has the potential to decrease the effect of antineoplastic drugs on brain tumors?

   A. Aprepitant

   B. Dexamethasone

   C. Granisetron

   D. Ondansetron

   Preferred response: B

Rationale

Corticosteroids, most commonly dexamethasone or methylprednisolone, are potent antiemetic agents and have a critical role in managing acute and delayed CINV in children. Their exact mechanism of action is unclear but may involve decreasing 5-HT_3 release in the periphery. However, corticosteroids also have the potential to decrease the effect of antineoplastic drugs on brain tumors, osteosarcomas, and carcinomas. Dexamethasone may augment the ability of a number of carcinomas to resist both radiation and chemotherapy. Interferon or interleukin-2 may be less effective when utilized along with steroids.

The first-generation 5-HT_3 receptor antagonists of dolasetron, granisetron, and ondansetron are most useful for CINV occurring within the first 24 hours after the administration of chemotherapy (acute CINV). They are equally effective and equally toxic, with the most common adverse effects being headache, constipation, and dizziness. At the appropriate doses, it has been established that the 5-HT_3 receptor antagonists are as effective when given orally as when given intravenously and that single daily dose schedules are as effective as multiple-dose schedules.

The neurokinin-1 receptor antagonist is the most recent antiemetic class. These antagonists are effective for both acute and delayed nausea and vomiting in persons undergoing moderately and highly emetogenic chemotherapy. Such agents are approved for use in persons with CINV only when they are used in conjunction with a 5-HT_3 antagonist and a corticosteroid. Examples are oral aprepitant and intravenous fosaprepitant. They are generally well tolerated, with diarrhea, fatigue, headache, and hiccups being common adverse effects. Both aprepitant and fosaprepitant are substrates and are inhibitors and inducers of the cytochrome P-450 enzymes 3A4 and 2C9.

4. A child is admitted to the PICU after resection of a brain tumor. Chemotherapy is initiated and a serotonin antagonist is administered as an antiemetic. After the first 24 hours, multiple episodes of vomiting develop. A computed tomography scan of the head rules out increased intracranial pressure. Which drug has been shown to safely improve the antiemetic effect of serotonin antagonists in children?

   A. Dexamethasone

   B. Diphenhydramine

C. Droperidol

D. Metoclopramide

Preferred response: A

Rationale

The serotonin receptor antagonists have been studied in the pediatric population for the prevention and treatment of postoperative nausea and vomiting, and they show similar efficacy. Ondansetron has been compared with the antihistamine group of antiemetics, with conflicting results. The addition of dexamethasone before an operation appears to prolong the antiemetic effect when compared with the serotonin antagonists alone. In patients pretreated with dexamethasone, dolasetron and ondansetron provide equivalent postoperative vomiting control. The addition of droperidol to granisetron also appears to improve antiemetic efficacy; however, the use of droperidol in pediatric patients has been discouraged because of the potential for adverse effects, including QT prolongation, torsades de pointes, hypotension, dysphoria, drowsiness, hyperactivity, extrapyramidal effects, and anxiety. Droperidol should be reserved for patients for whom first-line therapy has failed and who are hospital inpatients.

5. A child undergoing radiation therapy for treatment of a brain tumor has been receiving antiemetic medications when oculogyric crisis develops. Which of the following drugs is probably responsible for this type of manifestation?

A. Diphenhydramine

B. Granisetron

C. Hydroxyzine

D. Metoclopramide

Preferred response: D

Rationale

Adjuvant medications can be used in combination with serotonin receptor antagonists to optimize control of emesis when effectiveness is less than desired. Within the pediatric population, several of these medications are avoided because of their adverse effect profile. Most notably, agitation, sedation, and extrapyramidal reactions are seen with use of the phenothiazines and metoclopramide; oculogyric crisis is seen in particular.

6. Which of the following antiemetic medications is not routinely used in the pediatric population because of the risk of torsades des pointes and prolonged QT?

A. Diphenhydramine

B. Droperidol

C. Hydroxyzine

D. Metoclopramide

Preferred response: B

Rationale

Use of droperidol in pediatric patients has been discouraged because of the potential for adverse effects, including QT prolongation, torsades de pointes, hypotension, dysphoria, drowsiness, hyperactivity, extrapyramidal effects, and anxiety. Droperidol should be reserved for patients for whom first-line therapy has failed and who are hospital inpatients.

7. A 5-year-old child with a history of prolonged QTc syndrome is diagnosed with gastroesophageal reflux disease (GERD). Which of the following agents can exacerbate this child's cardiac issues?

   A. Cisapride

   B. Erythromycin

   C. Lansoprazole

   D. Metoclopramide

   Preferred response: A

Rationale

Prokinetic agents are of interest in GERD because of their ability to enhance esophageal peristalsis and accelerate gastric emptying. Cisapride is a prokinetic agent that at one time was widely used not only for GERD but also for a variety of adult and pediatric motility disorders, including constipation and gastroparesis. It was prescribed more frequently than metoclopramide in children, most likely because of its broader range of action and decreased risk of neurologic adverse effects. Prolongation of the QTc interval with potential life-threatening ventricular arrhythmias was reported when cisapride was used concomitantly with drugs that inhibit the hepatic cytochrome P-450-3A4 system. This uncommon yet potentially fatal adverse effect led the manufacturer to place it under a limited access protocol requiring close supervision by a pediatric gastroenterologist.

Erythromycin is a macrolide antibiotic and motilin agonist. It increases motility in the proximal gastrointestinal tract. The most frequent adverse effects of erythromycin include abdominal cramping, nausea, vomiting, diarrhea, cardiac dysrhythmias with interacting medications, and risk of bacterial overgrowth. Metoclopramide promotes gastric emptying by acting as an antagonist to the inhibitory actions of dopamine in the gut. It also sensitizes the gut to acetylcholine and increases lower esophageal sphincter tone. Metoclopramide blocks dopamine receptors in the chemoreceptor trigger zone and accelerates gastric emptying and intestinal transit time without stimulating gastric, biliary, or pancreatic secretions. Adverse effects are common, are dose dependent, and can include extrapyramidal effects, seizures, and parkinsonian reactions that may be irreversible.

Sucralfate, an aluminum salt of sulfated sucrose, forms a protective barrier by binding to damaged mucosa in an acidic environment. Although it has demonstrated effectiveness in the treatment of esophagitis, it is not recommended for long-term treatment of GERD in children because of a lack of efficacy data and safety concerns associated with aluminum toxicity

By covalently bonding to the hydrogen potassium-adenosine triphosphatase of parietal cells, proton pump inhibitors suppress gastric acid secretion for the life of

the parietal cell. Ideally, therapy should be given 30 minutes before feeding so that peak plasma concentrations coincide with parietal cell stimulation. Administration with food reduces bioavailability by 50%. Although their serum half-lives are relatively short, the pharmacologic effect persists until new parietal cells are generated. Omeprazole, esomeprazole, and lansoprazole have been approved for use in pediatrics.

8. Which of the following drugs is currently recommended for treatment of nonvariceal upper gastrointestinal bleeding?

   A. H_2-receptor antagonist

   B. Octreotide

   C. Proton pump inhibitor

   D. Somatostatin

   Preferred response: C

Rationale

Clinical guidelines for the treatment of nonvariceal upper gastrointestinal bleeding in adults include recommendations for pharmacotherapy. Unfortunately, this body of evidence does not exist in the pediatric population. H_2-receptor antagonist use is discouraged as primary treatment for patients with acute bleeding. Although octreotide and somatostatin are more effective than H_2-receptor antagonists, these agents also are not recommended for routine management. Proton pump inhibitors are cited as the drugs of choice for treatment of acute nonvariceal upper gastrointestinal bleeding. High-dose intravenous proton pump inhibitor therapy (80 mg pantoprazole bolus followed by 8 mg/hour for 72 hours after endoscopic therapy) is preferred over H_2-receptor antagonists alone, or in combination with octreotide, to prevent rebleeding in adult patients. As more data become available regarding the use of intravenous proton pump inhibitors in pediatric patients, parallels may be seen between the treatments of adult and pediatric nonvariceal upper gastrointestinal bleeding.

9. A 7-year-old girl with gastrointestinal bleeding of unknown etiology tested positive for *Helicobacter pylori*. What is the recommended first-line therapy for this patient?

   A. H_2-receptor antagonist + clarithromycin

   B. H_2-receptor antagonist + metronidazole

   C. H_2-receptor antagonist + tetracycline + ranitidine

   D. Proton pump inhibitor + clarithromycin + metronidazole

   Preferred response: D

Rationale

Patients who have gastrointestinal bleeding of unknown etiology should be tested for *H. pylori*. At minimum, therapy requires three different medications administered twice daily for 1 to 2 weeks. Three different regimens are recommended for first-line treatment in pediatrics. Each regimen consists of a proton pump inhibitor in

combination with amoxicillin and clarithromycin, amoxicillin and metronidazole, or metronidazole and clarithromycin. Second-line options incorporate bismuth subsalicylate or ranitidine and tetracycline as one of the antibiotic choices. Tetracycline is contraindicated in patients younger than 8 years because of permanent discoloration of teeth, enamel hypoplasia, and retardation of skeletal development and bone growth. Noncompliance with *H. pylori* regimens is the most commonly cited reason for treatment failure.

10. A 7-year-old child with a severe upper gastrointestinal bleed is admitted to your PICU, and an octreotide infusion is initiated. Which of the following is a possible adverse effect of this therapy?

A. Bradycardia

B. Constipation

C. Hypertension

D. Hypoglycemia

Preferred response: A

Rationale

Octreotide is a somatostatin analogue. Its pharmacologic actions include inhibition of gastric acid secretion and decreased splanchnic blood flow. Although its 1.7-hour half-life is approximately 30 times longer than that of somatostatin, octreotide is usually administered through continuous infusion for gastrointestinal hemorrhage. Adverse effects include abdominal pain, sinus bradycardia, nausea, pain at the site of injection, elevation of liver enzymes, chest pain, emesis, headache, dizziness, fatigue, flushing, and diarrhea. Long-term use (longer than 1 month) has been associated with changes in thyroid function, gallstone formation, and cholecystitis.

11. Which of the following medications may worsen hepatic encephalopathy in patients with liver failure?

A. Furosemide

B. Lactulose

C. Neomycin

D. Spironolactone

Preferred response: A

Rationale

In patients with hepatic encephalopathy, protein restriction to 2 to 3 g/kg/day may lessen excessive ammonia production, whereas fluid restriction to 75% of maintenance may prevent cerebral edema and reduce encephalopathy. Intravenous mannitol, continuous furosemide infusions, and tight glucose control also have been used to treat cerebral edema. Oral antibiotics, particularly neomycin, have been effective in reducing ammonia production in adults with hepatic encephalopathy by suppressing bacteria that form ammonia in the gut. However, neomycin should be used cautiously in children because of potential renal toxicity and deafness. Synthetic disaccharides such as lactulose are metabolized by bacteria in the colon to form organic acids that lower the colonic stool pH and trap diffusible ammonia, thus

decreasing serum ammonia levels. Lactulose forms the basis of therapy in children with hepatic encephalopathy and elevated serum ammonia levels.

The lowest effective diuretic dose should be used to decrease ascites in patients with liver failure. Spironolactone, furosemide, and thiazides have been used most commonly. Spironolactone selectively inhibits the effects of aldosterone on the distal renal tubule and collecting systems, which may be advantageous in combination with thiazide or loop diuretics, particularly if therapeutic end points are still not achieved after spironolactone dose escalation. The addition of a thiazide or loop diuretic increases the likelihood of adverse effects such as hypokalemia and metabolic alkalosis, which may precipitate hepatic encephalopathy by creating an environment that increases ammonia reabsorption.

Chapter 99: Acute Liver Failure, Liver Transplantation, and Extracorporeal Liver Support

---

1. A 5-year-old male presents with possible acute liver failure after a 1-week history of rhinorrhea, cough, and congestion, for which he has been taking acetaminophen. Upon presentation the following laboratory tests were obtained: INR, 4.0; total bilirubin, 19 μmol/L; aspartate aminotransferase (AST), 1243 U/L; alanine aminotransferase (ALT), 2810 U/L; WBC, 4×10^9/L; hemoglobin, 11.3 g/dL; hematocrit, 33%; platelets, 302×10^9/L; ammonia, 30 μmol/L; and gamma glutamyl transferase (GGT), 316 U/L. Evaluation in the emergency room demonstrates a child who appears tired, has no respiratory distress, and answers questions appropriately but slower than usual per parental report. Which of the following choices is correct regarding this patient?
   A. Admission or transfer to a liver transplantation center early on in the clinical course may decrease morbidity and mortality.
   B. Because the ammonia is normal, the patient's mental status is due to his viral illness and not developing hepatic encephalopathy.
   C. The cause of acute liver failure is definitely acetaminophen ingestion.
   D. The patient's prognosis is poor given the high laboratory values upon presentation.
   Preferred response: A

Rationale

Choice A is correct, because anticipation and early identification of patients who go on to need liver transplantation can help lessen poor outcomes. Choice B is incorrect because stage 1 hepatic encephalopathy can be subtle and may be confused with fatigue from other causes. Although trending ammonia may help with determining the progression of liver failure, there is not always a correlation between stages of encephalopathy and laboratory values. Parental observation and history may be better indicators of developing hepatic encephalopathy. Choice C is incorrect

because the causes of liver failure can include a multitude of etiologies and can be multifactorial. Given that the patient also presented with a viral prodrome, viral etiologies should also be considered. A thorough workup for various etiologies of liver failure should be initiated. Choice D is incorrect because prognostication is difficult to assess without knowing the trajectory of clinical course. Currently in pediatric acute liver failure, there remains a paucity of prognostic tools to determine outcome.

2. The previously mentioned 5-year-old male was then transferred to a pediatric liver transplantation center and received a left lateral segment liver transplant 1 week later due to worsening laboratory values and progression of hepatic encephalopathy. Which of the following is correct about the postoperative period?
   A. It should be anticipated that the patient will need substantial analgesia and sedation for many days because of the extensive surgical procedure he has undergone.
   B. Infection can be a major cause of morbidity post–liver transplant and the patient should be carefully assessed.
   C. There is no hurry to wean this patient from the ventilator after liver transplantation.
   D. Transaminitis without coagulopathy detected on postoperative day 5 is probably due to primary nonfunction of the allograft.
   Preferred response: B

Rationale

Sepsis is a major cause of morbidity given the degree of immunosuppression and abdominal surgery. Choice A is incorrect. The patient should be carefully assessed for discomfort and appropriately treated, but pain can be expected to resolve rapidly in the first few days. Excessive and prolonged use of sedative medication and opiate analgesia delays recovery and leads to the need for prolonged ventilator support and poor gastrointestinal motility. Choice C is incorrect because prolonged ventilator support is associated with increased complications, prolonged ICU stays, and delayed discharge from the hospital. Choice D is incorrect because primary liver dysfunction can present with transaminitis and should always be considered but if present is associated with coagulopathy immediately the operation and does not appear this late after implantation. Acute allograft rejection, major hepatic vessel thrombosis, infection, and biliary complications are among the differential diagnoses.

3. Which of the following coagulation factors is either normal or elevated in acute liver failure (ALF)?
   A. Factor II
   B. Factor V
   C. Factor VII
   D. Factor VIII
   Preferred response: D

Rationale

The coagulation factors synthesized by hepatocytes include factors I (fibrinogen), II (prothrombin), V, VII, IX, and X, and a reduction in synthesis leads to the prolongation of prothrombin and partial thromboplastin time.

The prothrombin time is the most clinically useful measure of hepatic synthesis of clotting factors. Prolongation of the prothrombin time often precedes other clinical evidence of hepatic failure, such as encephalopathy, and may alert the clinician to the severity of acute hepatitis; it is a guide to the urgency of liver transplantation. Fibrinogen (factor I) concentrations are usually normal unless there is increased consumption such as in disseminated intravascular coagulation (DIC). The level of factor VIII may help differentiate between DIC and ALF, as factor VIII is synthesized by vascular endothelium and therefore is normal or increased in ALF, as an acute-phase response or due to decreased utilization.

4. Which of the following is the most sensitive indicator of coagulopathy in the setting of acute liver failure?

   A. Decrease in factor VII

   B. Decrease in factor VIII

   C. Decrease in fibrinogen

   D. Prolongation of prothrombin time

   Preferred response: A

Rationale

The prothrombin time depends on the availability of factor VII, which has the shortest half-life ($t_{1/2}$ ≈4–7 hours) of the clotting factors and decreases more rapidly than other liver-derived clotting factors when production does not keep up with its utilization. As a result, measurement of factor VII is a more sensitive indicator than the prothrombin time but is typically not as readily available. Factor VIII is synthesized by vascular endothelium and therefore is normal or increased in acute liver failure.

5. A 6-year-old child is admitted to the PICU with acute liver failure due to acetaminophen ingestion. Laboratory results demonstrate platelet count, 53,000/μL; prothrombin time, 43 seconds; partial thromboplastin time, 65 seconds; hemoglobin, 8.5 g/dL; and fibrinogen, 120 mg/dL. The patient has oozing from the site of a line insertion. A computerized tomographic scan of the head rules out intracranial hemorrhage. Besides administering *N*-acetylcysteine, your next step in the management of this patient would be to transfuse which of the following?

   A. Cryoprecipitate

   B. Factor VIIa

   C. Fresh frozen plasma

   D. Platelets

   Preferred response: C

Rationale

Although in the early stages of assessment, prolongation of prothrombin time is a sensitive guide to prognosis and the need for liver transplantation, life-threatening coagulopathy should be corrected with fresh frozen plasma (FFP), platelets, and cryoprecipitate as needed. It is not necessary to maintain coagulation parameters (prothrombin time) in the normal range. In general, mild to moderate coagulopathy (prothrombin time <25 seconds) requires no therapy except support for procedures. Marked coagulopathy (prothrombin time >40 seconds) should be corrected (10 mL/kg of FFP every 6 hours) to prevent the risk of bleeding, particularly intracranial hemorrhage.

This child is not actively bleeding but has a prothrombin time of longer than 40 seconds, so she should receive FFP. Administration of recombinant factor VIIa corrects the coagulation defect in patients with acute liver failure for a period of 6 to 12 hours only. It is not warranted in this situation. Cryoprecipitate is used in patients with acute liver failure who have marked hypofibrinogenemia or are actively bleeding, or prior to invasive procedures.

Chapter 100: Acute Abdomen

---

1. Which of the following injuries mandates a laparotomy?
   A. Grade II splenic hematoma
   B. Grade II hepatic hematoma
   C. Grade I renal injury
   D. Intraperitoneal bladder rupture
   Preferred response: D

Rationale

Intraperitoneal bladder rupture requires laparotomy because the urine will continue to extravasate into the peritoneal cavity causing sepsis and increased BUN/creatinine. A laparotomy will allow the surgeon to close the laceration. Extraperitoneal bladder injuries have been shown to heal with simple catheter drainage of the bladder.

2. Outside of laparotomy, what is the best diagnostic modality to identify the specific nature and extent of blunt intraabdominal injury?
   A. Computed tomography (CT)
   B. Diagnostic laparoscopy
   C. Diagnostic peritoneal lavage
   D. Focused abdominal sonography for trauma
   Preferred response: A

Rationale

A CT scan is the only imaging modality listed to provide organ-specific information as to the location and extent of injuries in the abdomen.

3. A 3-year-old girl weighing 20 kg has been admitted to the intensive care unit for

management of sepsis following a 6-day course of fever and abdominal pain and an exploratory laparotomy 18 hours ago for a perforated appendicitis. She is receiving intravenous piperacillin and tazobactam and 80 mL/h of D5 in 0.45 saline solution. She has a fever of 38.8°C, is undergoing mechanical ventilation, has a heart rate of 120 beats per minute, and has a mean arterial pressure of 45 mm Hg. Her urine output is 50 mL during the past 8 hours. Which of the following is the most appropriate next step in her management?

A. Administer an intravenous saline solution bolus of 400 mL.

B. Administer an intravenous bolus of 10 mg of furosemide.

C. Change her antibiotics to broaden her antibiotic coverage.

D. Check her gastric pressure using the nasogastric tube.

Preferred response: A

Rationale

This patient underwent surgery only 18 hours ago for a severe intraabdominal infection and has fever, tachycardia, oliguria, and hypotension. Her intravenous fluid maintenance rate is only 96 mL per kg per day. The most likely explanation for oliguria within 24 hours of surgery is hypovolemia, and thus she should respond to an empiric bolus of fluid. Diuretic use should not be considered in the first 24 hours after surgery unless hypovolemia has been excluded. Although abdominal compartment syndrome could become a concern, it is unlikely at this early postoperative juncture. It is much easier to measure bladder pressure than intragastric pressure. The current antibiotic choice should be adequate for intraabdominal sepsis from appendicitis.

4. A 12-year-old, 55-kg boy presented 48 hours ago with midgut volvulus resulting in intestinal ischemia, which required resection of approximately half of his small intestine. His vital signs are as follows: heart rate, 100 beats per minute; blood pressure, 105/60 mm Hg; and pulse oximetry, 94% on 4 L of oxygen via nasal cannula with a fraction of inspired oxygen of 0.50. Arterial blood gas findings reveal the following values: pH, 7.24; $PaCO_2$, 36 mm Hg; PaO_2, 58 mm Hg; and HCO_3, 17 mmol/L. His urine output is 30 mL per hour. His amylase is 250 units/L (normal, <120 units/L), and his lactate level has been at 2.8 mmol/L (normal, <1 mmol/L) for 12 hours. Which of the following would be the most appropriate next step?

A. Administer sodium bicarbonate.

B. Obtain an abdominal and pelvic CT scan with enteral contrast.

C. Perform a colonoscopy.

D. Administer a surgical reexploration.

Preferred response: D

Rationale

This child had intestinal ischemia severe enough to warrant resection of a large segment of his small intestine. Therefore the entire midgut had compromised perfusion, including the bowel that was not resected. His acidosis and

hyperlactatemia are most likely due to persistent ischemia of the remaining bowel, and no diagnostic imaging test can accurately determine the viability of that bowel. Therefore a laparotomy is a reasonable diagnostic and therapeutic intervention. A colonoscopy would not answer the intestinal viability question, and the gaseous distension that might result from insufflation during the procedure could make the intestinal ischemia worse. Sodium bicarbonate will be of limited benefit in conditions of ongoing acid production by the ischemic bowel.

Chapter 101: the Innate Immune System

---

1. A 12.5-kg, 18-month-old is referred to the PICU from the ward with tachycardia and abdominal distention. He has been an inpatient for 3 days and initially presented with a 4-day history of a nonspecific febrile illness and rash, having had a viral illness a week before. He has been treated with empirical intravenous antibiotics and intravenous fluids for poor oral intake. He has also been noted to have a hemoglobin concentration of 7.9 g/dL, a white cell count below 4×10^9/L, and a platelet count of 49×10^6/L. There is no foreign travel history. On examination he has a respiratory rate of 45 per minute, oxygen saturations of 92% in room air, and he is grunting. His heart rate is 170 beats per minute, blood pressure is 109/76 mm Hg, and capillary refill is 2 seconds. His liver edge is 5 cm below the right costal margin, and his spleen is 4 cm below the left costal margin. He is awake and alert. He has a maculopapular rash over his trunk. His temperature is 103.4°C. Which of the following will you consider after initial resuscitation and stabilization?

   A. Send a serum ferritin level and arrange for a bone marrow aspirate.

   B. Start vitamin A supplementation for a presumed diagnosis of measles.

   C. Stop all intravenous antibiotics in case this is an allergic reaction.

   D. Treat empirically with artesunate and mefloquine.

   Preferred response: A

Rationale

This child has a history of prolonged fever (>7 days) with hepatosplenomegaly, pancytopenia, and a rash. He therefore has four of five required features of hemophagocytic lymphohistiocytosis. A serum ferritin level should be raised (typically >500 ng/mL). A hematologic malignancy must also be strongly suspected, for which a bone marrow aspirate will be informative. Measles does not cause hepatosplenomegaly. Given the lack of a travel history, malaria is unlikely but still possible. An allergic reaction is unlikely given that he has been on antibiotics for 3 days with preceding symptoms, and it does not cause a hepatosplenomegaly.

2. A 4.5-kg, 5-month-old child has been admitted to the PICU with septic shock following a 24-hour history of a cough and lethargy. His growth has been faltering, and he has presented to his family doctor three times for upper respiratory tract infections, including an episode of otitis media and tympanic

membrane perforation. There is no family history of medical problems, and the mother had normal screening during pregnancy. He has been started on broad-spectrum intravenous antibiotics. There is no history of a rash. There is no lymphadenopathy or hepatosplenomegaly on examination. Which of the following underlying diagnoses is the *most* likely?

A. C1 esterase inhibitor deficiency

B. HIV infection

C. Mannose binding lectin deficiency

D. Parental neglect

Preferred response: C

Rationale

The child has presented with recurrent upper respiratory tract infections very early in life, with faltering growth, making an underlying immunodeficiency common. Mannose binding lectin (MBL) deficiency is thought to be present in 5% to 10% of the population, and it is often present early in life with recurrent viral or bacterial upper respiratory tract infections. C1 esterase inhibitor deficiency causes an acquired angioedema. HIV infection is unlikely given normal maternal screening in pregnancy, and it is unlikely to present with symptoms of immunodeficiency so early in life. Parental neglect should be considered based on history and examination but must be a diagnosis of exclusion.

3. A 12-year-old boy with trisomy 21 is admitted to the PICU following insertion of a prosthetic mitral valve due to mitral valve incompetence. Within the first 12 hours his heart rate has risen from 100 beats per minute to 135 beats per minute. He is in sinus rhythm. His blood pressure is 97/56 mm Hg with a mean blood pressure of 70 mm Hg. His central venous saturations are 72%; his lactate, which was initially 3 mmol/L, has gradually dropped below 1 mmol/L. His urine output is 1.2 mL/kg/hr. No liver edge is palpable, and his central venous pressure (CVP) reading is 9 mm Hg. He is on milrinone of 0.5 micrograms/kg/min. His temperature is 100.5°F. Which set of actions would you choose to follow next?

A. Call the cardiac surgeon to reexplore the valve and to look for potential collections.

B. Escalate the antibiotics from prophylactic to a treatment regimen.

C. Give a fluid challenge for suspected low cardiac output, and consider adding in some epinephrine.

D. Manage the temperature, which is like to be secondary to a systemic inflammatory response.

Preferred response: D

Rationale

A systemic inflammatory response is common after any surgery, due to the release of damage-associated molecular pattern molecules (DAMPs). This is especially true post cardiac bypass. Although the child is currently in sinus rhythm, he is at risk of an arrhythmia post–cardiac surgery, and a high temperature can exacerbate this

result. Unlike in a patient with infection, the risk of the fever outweighs the benefits and should be managed. Escalation of antibiotic therapy may be too soon to consider within the first 12 hours, unless there are other markers of sepsis. A fever due to a low cardiac output state should be considered, although the hemodynamic variables do not suggest that this has occurred. Reexploration of the chest and valve is not warranted at this stage, as there are no signs of hemodynamic compromise.

4. A 4-week-old infant is admitted to the intensive care unit after arterial switch for congenital transposition of the great arteries. A systemic inflammatory response develops. This response is most likely due to which of the following?

   A. Hypothermia

   B. Intraoperative tissue damage

   C. Intravenous catheter insertion

   D. Preexisting upper respiratory tract infection

   Preferred response: B

Rationale

Endogenous ligands as a result of tissue damage (direct and hypoxic ischemia) will initiate an inflammatory response. This response is even more obvious in this child because she is relatively old for the procedure.

5. A previously healthy 3-month-old child with respiratory syncytial virus (RSV) bronchiolitis and shock is likely to have which of the following?

   A. Genetic predisposition to high proinflammatory cytokine production

   B. Hypovolemic shock

   C. Myocardial depression

   D. Pulmonary hypertension

   Preferred response: B

Rationale

RSV bronchiolitis usually remains a single-organ dysfunction, especially in a previously healthy child. Genetic polymorphisms in cytokine production have yet to be proved to be of major importance. This child has a high likelihood of reduced fluid intake and subsequent hypovolemia.

6. A 5-year-old child has a severe systemic inflammatory response 24 hours after multiple trauma from a pedestrian road traffic accident. Which of the following is an endogenous molecule that induces a proinflammatory response via pattern recognition receptors?

   A. Acetylcholine

   B. Fibrinogen

   C. Flagellin

   D. Lipoteichoic acid

   Preferred response: B

Rationale

Lipoteichoic acid and flagellin are *exogenous* ligands. Acetylcholine exerts an antiinflammatory effect.

7. Which of the following statements is correct regarding toll-like receptors (TLRs)?
   A. TLRs are part of our innate immune system.
   B. TLRs are part of the major histocompatibility complex class I (MHC-I) molecules.
   C. TLRs are part of the major histocompatibility complex class II (MHC-II) molecules.
   D. TLRs are activated by the alternative complement system.
   Preferred response: A

Rationale

Cells of the innate immune system use two systems for recognizing invading microorganisms. The first mechanism relies on the identification of pathogen-associated molecular patterns (PAMPs), which are microbial molecules primarily composed of lipids or carbohydrates that are essential to pathogen survival. The recognition of a microbial PAMP is coupled to prostimulatory signals that activate the innate immune response. The second mechanism used to detect microbes has been termed *recognition of missing self.* Normal uninfected host cells (but not microbial cells) express surface molecules, such as MHC-I molecules. Recognition of self-molecules such as MHC-I triggers inhibitory signals in cells that prevent innate immune activation.

TLRs appear to be the primary recognition receptors for microbial molecules (PAMPs). TLRs are expressed on many immune and nonimmune cells, including macrophages, platelets, and cardiac myocytes. This expression is modulated rapidly in response to pathogens and cytokines. Many of these TLRs (eg, TLR-1, TLR-2, TLR-4, and TLR-5) are expressed on the cell wall, whereas others are found intracellularly (eg, TLR-3, TLR-7, and TLR-9).

8. Which of the following is a pathogen-associated molecular pattern (PAMP) for TLR-4?
   A. Bacterial deoxyribonucleic acid (DNA)
   B. Double-stranded ribonucleic acid
   C. Lipopolysaccharide
   D. Lipoteichoic acid
   Preferred response: C

Rationale

TLR-4 is responsible for the recognition of endotoxin in mammals. TLR-4 is a protein that recognizes lipopolysaccharide (LPS) and is located on antigen-presenting cells (APCs) such as dendritic cells, macrophages, and monocytes. Through a complex signaling cascade, TLR-4 results in activation of cytoplasmic nuclear factor-κB (NF-κB), which can then move into the nucleus and induce the transcriptional activation

of a wide variety of inflammatory and immune responses. These responses include the induction of cytokines such as tumor necrosis factor-α (TNF-α), interleukin-1 (IL-1), IL-6, IL-12, and the induction of costimulatory molecules such as CD80 and CD86. The presentation of antigen by the MHC-II molecule on the APC is insufficient to induce the activation of the T-cell receptor and thus the T cell.

9. Toll-like receptor-4 (TLR-4) is present on which type of cell?
   A. Endothelial cells
   B. Macrophages
   C. Megakaryocyte
   D. Platelets
   Preferred response: B

Rationale

TLR-4 is a protein that recognizes lipopolysaccharide (LPS) and is located on antigen-presenting cells (APCs) such as dendritic cells, macrophages, and monocytes.

10. Which of the following toll-like receptors (TLRs) recognizes peptidoglycans and lipoteichoic acid of gram-positive bacteria?
   A. TLR-2
   B. TLR-4
   C. TLR-5
   D. TLR-6
   Preferred response: A

Rationale

TLR-2 recognizes essential components of gram-positive bacteria such as peptidoglycan and lipoteichoic acids and also recognizes cell wall components of yeast and mycobacteria. TLR-4 is responsible for the recognition of endotoxin in humans. TLR-5 is known to recognize flagellin, a monomeric constituent of flagella on bacteria such as *Listeria* and *Salmonella* organisms. TLR-6/TLR-2 recognizes the fungal cell wall component zymosan.

11. Toll-like receptor-5 (TLR-5) recognizes which pathogen molecule?
   A. Cell wall components of yeast
   B. Flagellin
   C. Lipopolysaccharide
   D. Lipoteichoic acid
   Preferred response: B

Rationale

TLR-5 is known to recognize flagellin, a monomeric constituent of flagella on bacteria such as *Listeria* and *Salmonella* organisms.

TABLE Q101.11

Components of the Innate Immune System

Pathogen Molecules	Innate Immune Receptors	Innate Immune Effectors
LPS		**Cells**
(gram-negative bacteria) →	TLR 4	Neutrophils
		Monocytes
RSV		Macrophages
Hsp 60		NK cells
Lipopeptides →	TLR 2	**Sentinel Cytokines**
Lipoteichoic acids		TNF-α
Peptidoglycans		IL-1
(gram-positive bacteria)		Chemokines
		NO
(Mycobacteria)		
(*Borrelia burgdorferi*)		**Late Response Cytokines**
Yeast		HMG-1
		MIF
		Innate Immunoproteins
CpG DNA →	TLR 9	MBL
		Complement
Flagellin →	TLR 5	BPI
		Defensins
		Lactoferrin
		CRP
		Procoagulants/Antifibrinolytic Tissue Factors
		PAI-1
		TAFI

12. Which of the following molecular pathogens can trigger an immune response through toll-like receptor-4 (TLR-4)?

A. Cell wall components of yeast

B. Flagellin

C. Lipoteichoic acid

D. Respiratory syncytial virus

Preferred response: D

Rationale

TLR-4 not only binds LPS but also the structurally unrelated fusion protein of respiratory syncytial virus (RSV) and *Plasmodium falciparum* glycosyl phosphatidylinositol. TLR-4 has been observed to ligate endogenous molecules such as heat shock proteins and fibrinogen. These interesting observations suggest that these pathways contribute to the ongoing immune response from other insults such as trauma rather than being specific to individual pathogens.

13. TLR-4 activation results in activation of which of the following factors responsible for the transcription of genes leading to production of proinflammatory cytokines IL-1 and TNF-α?

A. Nuclear factor-κB (NF-κB)

B. Factor Va

C. Factor VII

D. Factor Xa

Preferred response: A

Rationale

Through a complex signaling cascade, TLR-4 results in activation of cytoplasmic nuclear factor-κB (NF-κB), which can then move into the nucleus and induce the transcriptional activation of a wide variety of inflammatory and immune responses.

14. Systemic inflammatory response system (SIRS) caused by noninfectious insults can be clinically indistinguishable from SIRS due to infections, possibly because of the activation of TLR-4 by which of the following?

A. Complement

B. Heat shock protein 60

C. Lactoferrin

D. Nitric oxide

Preferred response: B

Rationale

Heat shock protein 60 has been shown to be a TLR-4 ligand, providing a direct explanation for why a variety of insults, including trauma and ischemia-reperfusion, trigger a SIRS similar to that due to infection. Based on this discussion it is clear that the phenotype of systemic inflammation caused by innate immune activation represents a general response to injury and invasion with a common set of molecular effectors.

15. Which of the following substances has been shown in animal models to be responsible for the four signs of inflammation in animals: calor, rubor, dolor, and tumor?

A. Bradykinin

B. C5a

C. Histamine

D. Kallikrein

Preferred response: A

Rationale

Bradykinin is an exceedingly potent vasoactive peptide. It can cause venular dilation, increased vascular permeability, hypotension, bronchoconstriction, and activation of phospholipase A_2. Bradykinin is metabolized by angiotensin-converting enzyme to inactive peptides. Bradykinin, along with prostanoids, stimulates the pain response through polymodal receptors and C fibers. In animal models, bradykinin has been shown to be responsible for the four signs of inflammation: heat, redness, swelling, and pain.

16. Which of the following is the only cytokine that has a natural inhibitor produced by the same cell?

A. IL-1

B. IL-6

C. IL-10

D. TNF-α

Preferred response: A

Rationale

IL-1 is the only cytokine with a natural inhibitor, IL-1 receptor antagonist, which is produced by the same cells that produce IL-1.

17. Increased susceptibility to infection by intracellular bacteria (*Listeria* and mycobacteria) and viruses (RSV, cytomegalovirus, and herpes simplex virus) can be due to a decrease in the production of which of the following?

A. Interferon-γ

B. Interleukin-1

C. Macrophage migration inhibitory factor

D. Tumor necrosis factor-α

Preferred response: A

Rationale

Interferon-γ (IFN-γ) has antiviral and antiproliferative activity. It up-regulates class I and II *human leukocyte antigen* (HLA) expression, thus enhancing cellular toxicity and antigen presentation, respectively. The activation by IFN-γ of monocytes, macrophages, and neutrophils results in enhanced killing of intracellular organisms, including mycobacteria and *Listeria.* In addition, IFN-γ induces inducible nitric oxide synthase in macrophages; the result is the generation of nitric oxide, a critical component for bactericidal function. Animals with a deficiency of IFN-γ have decreased survival in response to *Salmonella* and mycobacterial infections. Patients with complete loss of IFN-γ receptors have severe infections early in life with *Salmonella* and viruses (including RSV, parainfluenza, herpes simplex virus, and cytomegalovirus).

Chapter 102: Adaptive Immune System

---

1. You are caring for a 14-year-old girl who presents with fever, fluid-refractory hypotension, and erythroderma. You suspect toxic shock syndrome and consider adding intravenous immunoglobulin (IVIG) in addition to empiric antibiotic therapy. A medical student asks you why IVIG may be efficacious for toxic shock syndrome. What do you tell him?

A. The Fc portion of the delivered antibodies binds to inhibitory Fc receptors on B cells and innate immune cells, thus decreasing native antibody production and inflammation.

B. The delivered antibodies bind to and neutralize bacterial toxins, thus decreasing nonspecific T-cell/MHC molecule cross-linking.

C. The delivered antibodies provide long-lasting protective immunity against

Streptococcus and *Staphylococcus* species, the primary causes of toxic shock syndrome.

D. The delivered antibodies bind to Fc receptors on phagocytes that have ingested bacteria, augmenting microbial killing.

Preferred response: B

Rationale

Certain staphylococcal and streptococcal bacterial species are capable of producing toxins that function as superantigens. Superantigens crosslink T-cell receptors and major histocompatibility complex (MHC) molecules in a much less specific manner than is typically required for T-cell activation. In this way, larger numbers of T cells are activated at once, causing a systemic inflammatory response that manifests as the signs and symptoms of toxic shock syndrome. The major theoretic benefit of IVIG in this setting is to deliver toxin neutralizing antibodies to block microbial-derived superantigens. Response A describes the proposed mechanism for empiric IVIG treatment of autoimmune diseases, particularly those associated with autoantibodies. Response C is incorrect because intravenously administered immunoglobulins do not persist in the circulation long enough to provide lasting immunity. For response D, although antibody-mediated opsonization and augmentation of microbial killing may help control causative infection, this is not likely the most important mechanism of IVIG treatment for toxic shock syndrome.

2. Of the following, which does *not* describe a mechanism of peripheral T-cell tolerance?

   A. Antigen/MHC molecule recognition in the absence of costimulatory receptor binding

   B. Binding of the inhibitory T-cell costimulatory receptor, CTLA-4, to B7 molecules on antigen presenting cells

   C. Ingestion and destruction of self-reacting T cells by phagocytes

   D. Maintenance of a pool of $CD4^+$ immunosuppressive regulatory T cells (Treg)

   Preferred response: C

Rationale

Responses A, B, and D describe mechanisms of peripheral T-cell tolerance. Peripheral T-cell tolerance provides vital protection against autoimmune disease. Particularly, because $CD4^+$ helper T cells play integral roles in the activation and modulation of both cell-mediated and humoral immunity, peripheral tolerance of helper T cells may be especially relevant to autoimmune disease pathophysiology.

Chapter 103: Congenital Immunodeficiencies

---

1. A toddler is being evaluated for recurrent *Neisseria* infections. Which of the following tests would most likely be diagnostic for an associated

immunodeficiency?

A. Absolute $CD4^+$ count

B. CH50

C. Erythrocyte adenosine deaminase activity

D. IgG serum concentration

Preferred response: B

Rationale

CH50 provides an assessment of overall complement activity. Recurrent *Neisseria* infections are known to be associated with defects in the terminal complement pathway.

2. Which of the following immune cells are characterized by the production of reactive oxygen species as a host defense mechanism for foreign antigens and microbes?

A. B lymphocytes

B. Natural killer cells

C. Neutrophils

D. T lymphocytes

Preferred response: C

Rationale

Following activation, neutrophils and other phagocytes generate superoxide anion and several other reactive oxygen species as an aspect of the *respiratory burst* via NADPH oxidoreductase. Congenital absence of components of this enzyme complex results in chronic granulomatous disease.

3. A 6-year-old boy demonstrates anaphylaxis with a blood transfusion administered during surgery to resect a newly diagnosed brain tumor. Past medical history reveals involvement in a motor vehicle collision as a toddler resulting in multiple traumas and requiring a unit of transfused erythrocytes. Aside from his brain tumor the child has generally been healthy. Which of the following should be strongly considered as an underlying mechanism for the anaphylaxis?

   A. Ataxia-telangiectasia syndrome

   B. C1 esterase inhibitor deficiency

   C. Combined variable immune deficiency

   D. IgA deficiency

   Preferred response: D

Rationale

This child with IgA deficiency was likely sensitized with his first blood transfusion as a toddler. He subsequently developed anaphylaxis to IgA with his subsequent transfusion. Other potential diagnoses would all likely include some chronic comorbidity.

4. The only child of healthy parents is admitted at 4 months of age to the ICU with a 1-week history of loose, watery stools. Upon arrival he is dehydrated and in shock. On the fifth day of hospitalization, tachypnea and hypoxemia develop. The child was delivered at full-term after a normal pregnancy, labor, and delivery and had not been breast-fed. Previously he had been healthy and growing and thriving well. He received his 2-month immunizations without complications. He Two weeks prior to admission, he received his immunizations, including rotavirus vaccine, 2 weeks prior to admission. Examination reveals that he is pale and tachypneic, with 55 breaths per minute. His heart rate is 150 beats per minute. Pulses are easily accessible. Chest radiography shows diffuse perihilar reticular (interstitial) infiltrates and absent thymic shadow. A nasopharyngeal swab is positive for respiratory syncytial virus, and a complete blood cell count (CBC) on admission demonstrated a white blood cell count of 7.3×10^3 cells/μL (82% polymorphonuclear leukocytes, 5% bands, 8% lymphocytes, and 5% monocytes). A review of other studies demonstrates a low total protein level. What is the best course of action?

   A. Continue supportive care; bronchoalveolar lavage (BAL) is not indicated because the viral etiology has been identified.

   B. Determine quantitative immunoglobulins (IgG, IgA, IgM) and lymphocyte subpopulations; BAL may be indicated because of a concern for *Pneumocystis jirovecii* pneumonia.

C. Determine quantitative immunoglobulins (IgG, IgA, and IgM) and total hemolytic complement; BAL may be indicated because of a concern for bacterial superinfection.

D. Perform BAL only.

Preferred response: B

Rationale

The clinical scenario should suggest severe combined immunodeficiency syndrome (SCID) in the differential diagnosis. Male sex, age at presentation, live rotavirus vaccine given within a week of presentation, and subsequent severe diarrheal illness, lymphopenia, and absent thymic shadow on a chest x-ray are features of the clinical presentation of a child with SCID. The low total protein level is a clue for hypogammaglobulinemia, and thus quantitative immunoglobulins should be assessed. The diffuse interstitial pattern on a chest x-ray in a child with the indicated clinical and laboratory findings may suggest *P. jirovecii*. Determining lymphocyte subpopulations is essential to establishing the diagnosis of SCID. BAL may be indicated because *P. jirovecii* is a common presentation of children with SCID, and its diagnosis changes management procedures. In addition, coinfections with different organisms are seen commonly in children with SCID. This child does not display a classic presentation for a complement defect, because children with a complement defect have normal lymphocyte counts.

5. A 9-month-old girl is transferred to the intensive care unit from a community hospital. She has had a daily fever as high as 40°C for 8 days, progressive respiratory insufficiency, and persistent confluent right middle lobe and right lower lobe infiltrates. She has been treated for 5 days with azithromycin and for the past 3 days with ceftriaxone at the community hospital. Her medical history is significant for previous pneumonias and cervical adenitis. On examination, prominent cervical, axillary, and inguinal adenitis is found. A review of chest x-rays demonstrates no changes in confluent right middle lobe and right lower lobe infiltrates. A complete blood cell count reveals the following: hemoglobin, 10.5 g/dL, and white blood cells, 26,000/μL (60% polymorphonuclear cells, 15% bands, 5% monocytes, and 20% lymphocytes). IgG is 1800 mg/dL, IgA is 250 mg/dL, and IgM is 200 mg/dL. Her erythrocyte sedimentation rate is 85. Inspection of bronchoalveolar lavage fluid reveals gram-negative bacilli, probably a *Serratia* species, and blood cultures on admission also have identified gram-negative bacilli. Which of the following is the most likely diagnosis?

A. Chronic granulomatous disease

B. Common variable immunodeficiency

C. Hyper IgM

D. Leukocyte adhesion deficiency

Preferred response: A

Rationale

Nosocomial pneumonia due to *Serratia* species occurs less frequently in children than in adults. Infections with catalase-positive organisms are commonly seen in

patients with chronic granulomatous disease (CGD). Both X-linked and autosomal recessive forms of the disease have been described. *Serratia* species were a common cause of suppurative adenitis in an extensive report of 368 patients of CGD. Hypergammaglobulinemia is commonly seen in patients with CGD. IgG and IgA are low in persons with hyper IgM. The diagnosis of common variable immunodeficiency cannot be made in children who are younger than 2 years of age. Any child with community-acquired infection that is shown to be due to *Serratia* species should be evaluated for CGD.

6. A 6-month-old infant with failure to thrive is involved in a motor vehicle collision resulting in a grade III splenic laceration, but no other injury. In the setting of a declining hematocrit and progressive metabolic acidosis, the child receives a transfusion of packed erythrocytes (20 mL/kg). Results of admission laboratory studies include the following: hematocrit, 24%; hemoglobin, 8 g/dL; platelet count, 150,000/µL; white blood cell count, 9500/µL with a differential including 70% polymorphonuclear cells, 10% bands, 10% monocytes, and 10% lymphocytes; Na, 140 mEq/L; K, 3.5 mEq/L; Cl, 116 mEq/L; bicarbonate, 15 mEq/L; aspartate aminotransferase, 150 IU/L; alanine aminotransferase, 130 IU/L; and amylase, 75 units/L. Subsequently the child's hemodynamic status normalizes, and he is discharged from the hospital 5 days following the initial injury. Two weeks following discharge from the hospital, the child experiences a diffuse erythema with multiple bullous lesions, diarrhea, abdominal cramping, and scleral icterus. What is the most likely diagnosis?

   A. Cytomegalovirus infection

   B. Graft-versus-host disease

   C. Non-A, non-B hepatitis

   D. Peritoneal sepsis

   Preferred response: B

Rationale

This child initially presents with failure to thrive and absolute lymphopenia in addition to traumatic splenic laceration. Overwhelming and life-threatening graft-versus-host disease (GVHD) due to clonal expansion of donor-derived leukocytes present in the nonirradiated blood product can occur in children with severe combined immunodeficiency, which is the underlying diagnosis in this patient. Close evaluation of this patient might also reveal oral thrush in addition to classical manifestations of GVHD.

7. Which of the following is inconsistent with a diagnosis of DiGeorge syndrome (DGS)?

   A. Aortic arch anomaly

   B. Chromosomal 22q11 deletion

   C. Hypercalcemia

   D. Lymphopenia

   Preferred response: C

Rationale

DiGeorge syndrome (DGS) is recognized as a heterogeneous disorder characterized by a triad of clinical features: congenital heart disease, immunodeficiency, and hypocalcemia secondary to parathyroid dysplasia. Cytogenetic and molecular studies have demonstrated that in more than 90% of patients with DGS, a deletion of chromosomal region 22q11 occurs. Other genetic disorders such as velocardial facial syndrome and the conotruncal anomaly facial syndrome represent genetic syndromes with overlapping characteristics with DGS. Common features of children with the 22q11 syndrome are facial characteristics (small dysmorphic ears, narrow upslanted palpebral fissures, prominent nose with large tip and hypoplastic nares, periorbital fullness); midline defects including palatal abnormalities, cleft lip, and palate; swallowing difficulties; umbilical hernia; skeletal, renal, and urogenital anomalies; learning disabilities; and neuropsychiatric disorders.

Chapter 104: Acquired Immune Dysfunction

---

1. A 9-year-old boy who had a liver transplant at 1 year of age for biliary atresia presents to the emergency department with a 2-day history of fever. His vital signs at presentation are temperature, 38.8°C; heart rate, 168 beats per minute; blood pressure, 86/40 mm Hg; respiratory rate, 33 per minute; and pulse oximetry, 94% in room air. His current medication regimen is tacrolimus twice a day, trimethoprim and sulfamethoxazole three times per week, esomeprazole twice a day, and a tapering dose of prednisolone for a recent history of acute rejection status posttreatment. He received intravenous broad-spectrum antimicrobials in the emergency department, and his mental status deteriorated; he required aggressive fluid support to manage worsening hypotension. He was admitted to the PICU after intubation for acute respiratory failure and norepinephrine infusion for septic distributive shock. What laboratory finding is the *most* likely indicator of increased mortality?

   A. Decreased free T4 level

   B. Elevated C-reactive protein

   C. Elevated TNF-α serum levels

   D. Persistent lymphopenia

   Preferred response: D

Rationale

Sepsis is a devastating illness with mortality in pediatrics estimated to be 10% (Goldstein et al. International pediatric sepsis consensus conference: definitions for sepsis and organ dysfunction in pediatrics. Pediatr Crit Care Med. 2005:6:2-8). Sepsis is a process of proinflammatory and antiinflammatory activation and can lead to prolonged immunosuppression, increasing a patient's risk of secondary infections and mortality. If prolonged immunosuppression occurs, a patient's ability to clear

subsequent infectious processes remains impaired. Persistent lymphopenia is a strongly associated predictor of mortality after the diagnosis of septic shock. Drewry and colleagues demonstrated increased mortality rates if the patient has persistent lymphopenia 4 days after the diagnosis of septic shock. Serum cytokine levels in septic patients have been extensively studied and TNF-α serum levels may indeed be elevated, but TNF-α serum levels have not been conclusively associated with increased mortality. Sick euthyroid does occur in critically ill patients but is not a laboratory finding associated with increased mortality in septic shock.

2. A 4-month-old boy presents to the emergency department with progressive pulmonary insufficiency. His initial symptoms were cough and fever 1 week prior. He later developed tachypnea, decreased oral intake, and retractions 2 days ago. His vital signs are temperature, 38.5°C; heart rate, 155 beats per minute; blood pressure, 91/55 mm Hg; respiratory rate, 63 per minute; and pulse oximetry, 86% on a facemask with 6 L/min flow. Auscultation demonstrates good air movement with scattered wheezing and rales; no murmurs, clicks, or rubs have been noted. A chest radiograph reveals mild bilateral diffuse interstitial infiltrates and a normal cardiac silhouette. Laboratory results demonstrate white blood cell count of 6×10^9 per liter; hemoglobin, 11.3 g/dL; hematocrit, 35%; platelet count, 223×10^9 per liter; neutrophils, 80%; lymphocytes, 5%; monocytes, 12%; and eosinophils, 3%. He was born full term via spontaneous vaginal delivery to a mother who did not receive prenatal care. He has been healthy prior to this recent illness. He is breast-fed and started pureed foods. The Department of Children and Families (DCF) has been involved with the family because of a history of maternal substance abuse. What additional test should be ordered?

   A. Computed tomography (CT) of the chest

   B. Echocardiography

   C. Human immunodeficiency virus (HIV) polymerase chain reaction (PCR)

   D. Pro–brain natriuretic peptide (BNP)

   Preferred response: C

Rationale

This infant boy is presenting with hypoxemic respiratory failure and chest radiograph findings suggestive of *Pneumocystis jirovecii* pneumonia. This is an AIDS-defining illness and can be confirmed with an HIV PCR. Clinical data suggestive of pneumocystis are the cough, fever, tachypnea, profound hypoxemia on significant supplemental oxygen therapy, and a chest radiograph with mild pulmonary involvement. Clinical data suggestive of HIV/AIDS include an absolute lymphocyte count below 200 cells per microliter. Associated risk factors indicating increased likelihood of HIV are maternal history of substance abuse and no prenatal care during the pregnancy. *Pneumocystis jirovecii* pneumonia is the most common pathogen causing respiratory insufficiency in untreated HIV patients. It commonly presents after the decline of passive immunity from maternal antibody. An HIV PCR needs to be sent because the infant is still breast-feeding. In this case, the enzyme-linked immunosorbent assay (ELISA) may be falsely positive. This infant has a normal cardiac silhouette on the chest radiograph, so the utility of an echocardiogram or pro-BNP is questionable and will not explain his significant

hypoxemia. A chest CT may provide additional information about the lung disease, but it will not provide an etiology and therefore will not guide treatment.

3. A 3-month-old child with respiratory failure is transferred to the PICU from an outlying hospital. The child has failed to respond to broad-spectrum antibiotic therapy and is requiring escalating airway pressures to maintain adequate oxygen saturation. On further examination, you know that the infant has lymphadenopathy, hepatosplenomegaly, and failure to thrive. The complete blood cell count (CBC) shows a low normal absolute lymphocyte count and mild anemia. Which of the following statements is true?
   A. Culture of fluid obtained by gastric lavage for mycobacterium has a greater yield than that obtained by alveolar lavage.
   B. Rapid human immunodeficiency virus (HIV) testing by an enzyme-linked immunosorbent assay is the preferred mode of testing for HIV infection in this age group.
   C. Testing for *Pneumocystis jirovecii* requires a sample obtained by bronchoalveolar lavage.
   D. Trimethoprim and sulfamethoxazole should be administered at a dose of 20 mg/kg/day.
   Preferred response: D

Rationale

In endotracheally intubated patients, gastric lavage likely has a lower yield or the same yield but not a higher yield than alveolar lavage. Children with *P. jirovecii* pneumonia have abundant organisms and often can be diagnosed with sputum induction. Because of maternal antibodies present in infants, testing for HIV deoxyribonucleic acid or ribonucleic acid is preferred.

4. A 10-month-old child with cerebral palsy experiences respiratory failure as a result of respiratory syncytial virus. After showing initial improvement, the patient requires increased respiratory support for hypoxemia. Secretions from the patient's endotracheal tube are clear, and the Gram stain of the secretions shows few white blood cells (WBCs) and no bacteria. The total WBC count is normal, but the absolute lymphocyte count is 200 cells/μL. Which of the following statements is true?
   A. If the child had normal lymphocyte counts in the past, it is likely that the lymphopenia is a result of the respiratory syncytial virus infection.
   B. A secondary bacterial infection is likely, and the child should be treated with broad-spectrum antibiotics.
   C. If cytomegalovirus is recovered from the endotracheal tube, treatment with ganciclovir should be initiated.
   D. The child should be evaluated for chronic granulomatous disease as an etiology for this immunodeficiency.
   Preferred response: A

Rationale

A change in sputum color, quantity, or bacteria on the Gram stain would be seen in a bacterial infection. The diagnosis of cytomegalovirus pneumonia requires the visualization of intracellular viral inclusion bodies in alveolar macrophages. It would be appropriate to evaluate the child for HIV infection but not granulomatous disease.

Chapter 105: Immune Balance in Critical Illness: SIRS, CARS, Immune Paralysis

---

1. Which of the following immunologic test results is *most* strongly associated with the immunoparalyzed phenotype?
   A. Absolute lymphocyte count >1000 cells/uL
   B. Low plasma IL-6 level
   C. Markedly elevated ex vivo lipopolysaccharide (LPS)-induced TNF-α production capacity
   D. Monocyte HLA-DR expression of 20%
   Preferred response: D

Rationale

Monocyte HLA-DR expression <30% has been repeatedly associated with increased risks for secondary infection and death from multiple forms of critical illness. The immunoparalyzed phenotype is often associated with reduced ex vivo lipopolysaccharide (LPS)-induced TNF-α production capacity and high levels of circulating proinflammatory and antiinflammatory cytokines. Lymphopenia, as defined by an absolute lymphocyte count <1000 cells/uL, is a measure of adaptive immune suppression that is also consistent with immunoparalysis.

2. Which statement *best* describes the dynamic inflammatory response in critical illness?
   A. A marked and persistent CARS response is beneficial to the patient.
   B. Restoration of the SIRS/CARS balance can require immunostimulatory treatment.
   C. The CARS response affects the adaptive immune system more than the innate.
   D. The SIRS/CARS balance is easily quantified in the clinical laboratory.
   Preferred response: B

Rationale

The systemic inflammatory response syndrome/compensatory antiinflammatory syndrome (SIRS/CARS) balance can be measured through specialized testing of cytokines as well as markers of innate immune cell function such as monocyte HLA-DR expression and ex vivo LPS-induced cytokine production capacity. High levels of

systemic inflammation (SIRS) and immune suppression (CARS) often occur simultaneously, with a marked and persistent CARS response being frequently associated with adverse outcomes from critical illness. Restoration of immunologic homeostasis in the setting of CARS can sometimes be achieved by treatment with immunostimulatory agents like interferon gamma (IFN-γ) or granulocyte macrophage colony stimulating factor (GM-CSF).

Chapter 106: Pediatric Rheumatic Disease: Diagnosis, Treatment, and Complications

---

1. Macrophage activation syndrome is a severe complication of several rheumatic diseases characterized by which laboratory findings?
   A. Cytopenias, hyperferritinemia, hypofibrinogenemia, dropping ESR, elevated LDH
   B. Cytopenias, hypoferritinemia, hypofibrinogenemia, elevated ESR, elevated LDH
   C. Leukocytosis, hyperferritinemia, hypofibrinogenemia, dropping ESR, dropping LDH
   D. Leukocytosis, hypoferritinemia, hypofibrinogenemia, elevated ESR, dropping LDH
   Preferred response: A

Rationale

Macrophage activation syndrome (MAS) is a life-threatening complication of rheumatic diseases, particularly systemic-onset juvenile idiopathic arthritis (JIA). It presents with unremitting fevers, lymphadenopathy, hepatosplenomegaly, cytopenias, coagulopathy, and altered mental status. Laboratory testing is helpful in diagnosing MAS, and typical features include cytopenias (at least two of three cell lines), transaminitis, coagulopathy, elevated triglycerides, elevated LDH, a highly elevated ferritin level, a falling ESR, low fibrinogen, low or absent natural killer cell activity, and elevated soluble IL-2 receptor levels. The pathognomic feature of MAS is hemophagocytosis on bone marrow aspirate or biopsy.

2. In critically ill patients with rheumatic diseases, such as systemic lupus erythematosus, granulomatosis with polyangiitis, catastrophic antiphospholipid antibody syndrome, and macrophage activation syndrome, which of the following therapies is *not* typically part of the initial management in the ICU?
   A. Azathioprine
   B. Cyclophosphamide
   C. High-dose IV pulse methylprednisolone
   D. Rituximab
   Preferred response: A

Rationale

Aggressive treatment is essential and can be lifesaving in severely ill patients with newly diagnosed or flaring rheumatic diseases. In the ICU setting, treatment is typically initiated with high-dose pulse IV methylprednisolone (30 mg/kg/day, maximum dose 1000 mg), administered over 1 hour for 3 consecutive days. In addition to steroids, agents such as cyclophosphamide and rituximab are also used in patients with severe disease. Plasmapheresis is an additional therapy that has been shown to reduce mortality rates in several of the rheumatic diseases. Although azathioprine is an important therapy, it is typically used in patients with less severe disease as well as for long-term disease control. It is rarely introduced in the ICU-setting.

3. A 6-year-old boy with known systemic onset juvenile arthritis that was previously well controlled with low-dose prednisone and methotrexate has recently had an intercurrent illness from which he has been slow to recover. During the 24 hours prior to admission, he has become progressively more lethargic, has had a sustained fever to 38.9°C, and has bruised and bled easily. Laboratory studies in the emergency department before transfer to the intensive care unit show an erythrocyte sedimentation rate of 26 mm/hour (the last recorded value 1 month earlier was 54 mm/hour), prolonged prothrombin time and partial thromboplastin time, a platelet count of 20,000/μL, and an aspartate aminotransferase and alanine aminotransferase value of greater than 2000 IU/L. Which two additional diagnostic tests should be included in the initial workup of this patient to confirm the diagnosis and guide medical management?

   A. Complement levels and antinuclear antibody (ANA)

   B. Creatinine and renal biopsy

   C. Ferritin and bone marrow aspiration

   D. White blood cell count and hematocrit

   Preferred response: C

Rationale

This boy most likely has macrophage activation syndrome, a complication of his systemic onset juvenile idiopathic arthritis, possibly precipitated by an intercurrent infection. Further tests to confirm this diagnosis include a ferritin level test, which is usually markedly elevated, and a bone marrow aspiration to demonstrate the typical hemophagocytic changes. The differential diagnosis includes an infectious process causing disseminated intravascular coagulation. He should be treated with empiric antibiotics, although therapy for macrophage activation syndrome is initiated, which includes pulses of methylprednisolone, 30 mg/kg/day, and cyclosporine, 3 to 5 mg/kg/day. In addition, he should receive supportive therapies, such as correction of his coagulopathy.

4. A 14-year-old girl is admitted to the intensive care unit because of a 2-week history of fevers (now as high as 40.4°C), hypotension, and severe oral ulceration resulting in difficulty maintaining oral intake. Upon careful inspection, her physical examination reveals a pericardial friction rub, erythematous papules with scaling on her chest, and a swollen left knee. Her complete blood cell count shows a

hemoglobin level of 8.6 g/dL, a white blood cell count of 6600/µL with a left shift, and a platelet count of 120,000/µL. Her urine output is reduced, and her urinalysis shows proteinuria and hematuria. Her erythrocyte sedimentation rate is 86 mm/hour, and her C-reactive protein level is 1.2 mg/dL. What additional laboratory test results may help to confirm the diagnosis?

A. Elevated complement levels and a negative ANA test

B. A weakly positive ANA test and a positive anti-nuclear cytoplasmic antibody test (ANCA)

C. Low complement levels and a positive anti–double-stranded deoxyribonucleic acid (anti-dsDNA) antibody test

D. Normal complement levels and a positive ANCA test

Preferred response: C

Rationale

Although this girl could have a severe viral or bacterial infection, systemic lupus erythematosus also should be considered, given her age, gender, the discrepancy between her erythrocyte sedimentation rate and C-reactive protein level, anemia, and relatively low white blood cell count given the severity of her illness. In addition to the oral ulcers, multiple physical examination findings lead to consideration of the diagnosis of systemic lupus erythematosus, including malar rash, discoid rash, photosensitivity rash, joint swelling, and any evidence of serositis, dull lung bases consistent with pleural effusions, or pericardial friction rubs. In addition to evaluating and empirically treating her for a severe bacterial or viral infection, an ANA, dsDNA antibody, and complement levels should be ordered. Table Q106.4A describes the most likely autoantibody profiles in different rheumatologic diseases. In this patient, a careful evaluation of other organ systems, especially her kidneys given the proteinuria and hematuria, also is indicated. Table Q106.4B describes all the clinical criteria that are necessary to confirm the diagnosis of systemic lupus erythematosus.

5. A 15-year-old girl who recently arrived from a refugee camp in Africa is admitted from the emergency department because of severe respiratory distress. She is severely anemic (hemoglobin, 4.9 g/dL), and her chest radiograph shows generalized patchy infiltrates. She has no gastrointestinal symptoms, and a rectal examination is negative for occult blood. Her urinalysis shows red cells and 3+ proteinuria. The primary indication for emergently ordering blood products for this patient includes which of the following?

A. She needs an emergent blood transfusion because of heart failure caused by severe anemia.

B. She may have an occult upper gastrointestinal hemorrhage that has become life-threatening.

C. She may have catastrophic bleeding following a renal biopsy that is indicated to diagnose her underlying disease process.

D. She may have a life-threatening pulmonary hemorrhage resulting from an underlying pulmonary-renal syndrome.

TABLE Q106.4A

Autoantibody Profiles of Rheumatologic Diseases

	ANA	ds-DNA	Smith	ANCA	Complement
SLE	Strongly positive	Positive in 40% to 80% of cases	Positive in 50% to 60% of cases	Usually negative	Low
Wegener granulomatosis	Negative or weakly positive	Negative	Negative	Positive in 90% of cases (proteinase-3)	Normal
Microscopic polyangiitis	Negative or weakly positive	Negative	Negative	Positive in 90% of cases (myeloperoxidase)	Normal
Polyarteritis	Negative	Negative	Negative	Usually negative	Normal
Takayasu arteritis	Negative	Negative	Negative	Negative	Normal
JIA (systemic)	Negative	Negative	Negative	Negative	Normal to high

ANA, Antinuclear antibodies; ANCA, antinuclear cytoplasmic antibody test; dsDNA, double-stranded deoxyribonucleic acid; JIA, juvenile arthritis; SLE, systemic lupus erythematosus.

TABLE Q106.4B

Revised SLE Classifi cation Criteria

For the purpose of identifying patients in clinical studies, a person shall be said to have SLE if any of four or more criteria are present, serially or simultaneously, during any interval of observation.
1. Malar rash: Fixed erythema, fl at or raised, over the malar eminences, tending to spare the nasolabial folds 2. Discoid rash: Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring (may occur in older lesions) 3. Photosensitivity: Skin rash as a result of unusual reaction to sunlight, by patient's history or physician's observation 4. Oral ulcers: Oral or nasopharyngeal ulceration, usually painless, observed by a physician 5. Arthritis: Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion 6. Serositis a. Pleuritis, a convincing history of pleuritic pain, or rub heard by a physician or evidence of pleural effusion *or* b. Pericarditis with or without documentation by electrocardiogram or rub or evidence of pericardial effusion 7. Renal disorder a. Persistent proteinuria >0.5 g/day or greater than 3+ if quantitation not performed, *or* b. Cellular casts (may be red cell, hemoglobin, granular, tubular, or mixed) 8. Neurologic disorder a. Seizures in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance), *or* b. Psychosis in the absence of offending drugs or known metabolic derangements (e.g., uremia, ketoacidosis, or electrolyte imbalance) 9. Hematologic disorder a. Hemolytic anemia with reticulocytosis, *or* b. Leukopenia <4000/mm^3 total on two or more occasions, *or* c. Lymphopenia <1500/mm^3 on two or more occasions, *or* d. Thrombocytopenia <100, 000/mm^3 in the absence of offending drugs 10. Immunologic disorder a. Anti-DNA: Antibody to native DNA in abnormal titer, *or* b. Anti-SM: Presence of antibody to Sm nuclear antigen, *or* c. Positive fi nding of antiphospholipid antibodies based on: 1. An abnormal serum level of immunoglobulin G or immunoglobulin M anticardiolipin antibodies, *or* 2. A positive test result for lupus anticoagulant using a standard method, *or* 3. A false-positive serologic test result for syphilis known to be positive for at least 6 months and confi rmed by *Treponema pallidum* immobilization or fl uorescent treponemal antibody absorption test 11. An abnormal titer of ANA by immunofl uorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with drug-induced lupus syndrome.

From Hochberg MC: Updating the American College of Rheumatology revised criteria for the classifi cation of systemic lupus erythematosus, *Arthritis Rheum* 40:1725, 1997.

Preferred response: D

Rationale

Although the differential diagnosis for this patient includes iron deficiency anemia, malnutrition with severe infection, a marrow infiltrative process or aplasia, severe hemolytic anemia, or acute blood loss, a pulmonary-renal syndrome with life-threatening pulmonary hemorrhage should be suspected. Besides a full review of all organ systems and evaluation for other causes of her symptoms, this patient should be tested for Goodpasture syndrome (antiglomerular basement membrane antibodies), a vasculitic syndrome such as Wegener granulomatosis or microscopic polyangiitis (ANCA, proteinase-3, and myeloperoxidase), and lupus (ANA, complements, and dsDNA antibodies). Q106.4B summarizes the pulmonary, renal, and laboratory findings in the most common pulmonary-renal syndromes. Supportive therapy, which may require intubation, mechanical ventilation with high positive end-expiratory pressure, and blood transfusions, should be initiated for this patient. Clinical judgment regarding treatment with corticosteroids and other immunosuppressive therapies in addition to antibiotics is indicated.

Chapter 107: Bacterial and Fungal Infections; Antimicrobials; Antimicrobial Resistance

---

1. A previously healthy 3-year-old child presents with a 2-day history of fever, two episodes of emesis, mild sore throat, and decreased urine output. She is admitted to PICU with confusion, cool extremities, tachycardia, and an excoriated, crusted-over bug bite on the leg with surrounding erythema. Laboratory tests revealed elevated white blood cell count, elevated transaminases, and a lactate of 6 mmol/L. Preliminary blood culture grows gram-positive cocci in chains. You suspect toxic shock. Which antimicrobial should be added to her current regimen of vancomycin and ceftriaxone to enhance efficacy?

   A. Clindamycin

   B. Gentamicin

   C. Linezolid

   D. Piperacillin-tazobactam

   Preferred response: A

Rationale

A member of the lincosamide family, clindamycin inhibits the growth of bacteria by binding to the 50S subunit of the ribosome. In children with infection caused by strains of *S. aureus* or group A *Streptococcus* that are suspected to produce toxin-mediated disease (eg, toxic shock syndrome, necrotizing fasciitis), clindamycin is often used in conjunction with a β-lactam agent to stop toxin production as quickly as possible. Retrospectively collected data suggest improved outcomes in patients treated with the combination. Gentamicin is utilized as combination therapy for enhanced gram-negative coverage as is piperacillin-tazobactam—existing limited to no coverage of gram-positive bacteria. The macrolide azithromycin has enhanced

efficacy for atypical organisms and respiratory infections. Linezolid would be an appropriate choice for a vancomycin-resistant organism.

2. A 10-year-old boy with acute lymphoblastic leukemia is transferred to the PICU from the oncology ward with fever, neutropenia, progressive dyspnea, and hypoxia with progressive infiltrates on chest radiograph. He has been on broad-spectrum antimicrobials, and you suspect invasive pulmonary aspergillosis. Which antifungal would be ineffective in this patient?

   A. Amphotericin B

   B. Caspofungin

   C. Fluconazole

   D. Voriconazole

   Preferred response: C

Rationale

Fluconazole has no activity against *Aspergillus*. Voriconazole is available in both parenteral and enteral formulations and remains the drug of choice for invasive aspergillosis. Amphotericin and liposomal amphotericin, both FDA approved for *Aspergillus* infection, are excellent alternative therapies. Amphotericin has numerous side effects, but the liposomal caspofungin—an echinocandin, although not recommended as first-line therapy—is FDA approved as salvage treatment for invasive aspergillosis, and there is some clinical data suggesting benefit when used in combination with voriconazole as part of the initial treatment of invasive aspergillosis

Chapter 108: Life-Threatening Viral Diseases and Their Treatment

---

1. A previously healthy 9-year-old female has a history of fever and has had upper symptoms of an upper respiratory tract infection for 4 days. On presentation she complains of shortness of breath, abdominal pain, and emesis. Physical examination reveals a tired-appearing child with tachycardia and tachypnea. She has nasal congestion, bilateral fine crackles on lung exam, and a gallop rhythm and ejection systolic murmur on cardiac exam. Her abdominal exam is normal. Which of the following is *not* a useful modality to support a diagnosis of acute myocarditis?

   A. Chest radiograph (CXR)

   B. Computed tomography (CT) of the chest

   C. Echocardiogram

   D. Electrocardiogram (ECG)

   Preferred response: B

Rationale

There is a wide spectrum in the clinical manifestations of myocarditis in children. Findings of congestive heart failure are the most common feature. CXR will reveal pulmonary edema and possibly cardiomegaly; ECG may characteristically show ST-T wave changes and dysrhythmias. MRI and echocardiogram are used to demonstrate decreased contractility, ischemic changes, and pericarditis. Chest CT scan is generally not used in the diagnosis of myocarditis.

2. A previously healthy, immunized, 12-year-old male is admitted to the PICU. For 5 days he has had fever, fatigue, and headache and has had vomiting and lethargy for 2 days. On the day of admission he had a 1-minute focal tonic-clonic seizure. History is remarkable for a recent summer vacation trip to the northeastern United States where he spent a significant time outside and had many mosquito bites. Examination reveals fever, somnolence, nuchal rigidity, and a faint maculopapular rash on the trunk and extremities. Lumbar puncture reveals 40 white blood cells with 90% lymphocytes; protein, 75 mg/dL; and glucose, 60 mg/dL. Cerebrospinal fluid (CSF) Gram stain is negative. Enterovirus and herpes simplex virus (HSV) polymerase chain reaction (PCR) from the CSF are also negative. Which of the following tests is most likely to reveal the diagnosis?

   A. Acute and convalescent West Nile virus IgG and IgM from serum

   B. Adenovirus PCR of the CSF

   C. Rabies virus immunofluorescent microscopy from a skin biopsy

   D. Measles virus IgG and IgM from serum

   Preferred response: A

Rationale

This patient has West Nile (WN) meningoencephalitis. WN virus is an arbovirus transmitted by mosquitoes and generally has a seasonal distribution in the summer. Rash is a common feature but not necessary. Aseptic meningitis, encephalitis, and acute flaccid paralysis are among the neurologic complications of West Nile infection. HSV and enterovirus encephalitis are less likely in a patient with negative CSF PCRs. Rabies virus encephalitis is rare but should be considered in the differential diagnosis of acute encephalitis. Measles encephalitis is unlikely in the setting of an immunized child, especially without cough and conjunctivitis. Finally, adenovirus rarely causes meningoencephalitis. CSF viral culture is not a sensitive method of diagnosis.

3. If herpes simplex virus (HSV) encephalitis or neonatal disease is suspected, the most important initial step is to do which of the following?

   A. Determine the source of the exposure.

   B. Initiate empiric treatment with intravenous acyclovir.

   C. Initiate appropriate infection control precautions.

   D. Obtain diagnostic specimens including cerebrospinal fluid for HSV polymerase chain reaction.

   Preferred response: B

Rationale

When it is untreated, HSV encephalitis carries a death rate in excess of 70%, and even when it is treated, death and complications for those who survive remain on the order of 15% and 20%, respectively. Similarly, despite treatment, neonatal HSV central nervous system disease carries a significant risk of death and morbidity, ranging from 0% to 15% and 43% to 68%, respectively. Early identification of patients and rapid initiation of acyclovir have been associated with a better outcome. Unless an alternative cause is clear, high-dose acyclovir should be initiated in all children with encephalitis until HSV can be ruled out.

4. Direct detection (direct fluorescent antibody, culture, or polymerase chain reaction) of the viral pathogen is most important in the diagnosis of which of the following?

   A. Neonatal herpes simplex virus infection

   B. West Nile virus encephalitis

   C. Hepatitis A

   D. Acute measles infection

   Preferred response: A

Rationale

TABLE Q108.4

Potential Diagnostic Tests and Corresponding Specimens for Diagnosis of Viral Pathogens

Viral Agent	Specimen	Recommended Diagnostic Tests
Arboviruses (California encephalitis, Colorado tick fever, EEE, SLE, WEE, West Nile virus)	Serum (acute and convalescent)/plasma CSF	IgM and IgG antibody, PCR, and immunohistochemistry for some IgM and IgG antibody, PCR
EBV	Serum Plasma, CSF Tissue	IgM antibody or slide agglutination test (monospot) PCR PCR, immunohistochemistry
HSV I and II	CSF, plasma Base of lesion, NP, conjunctiva, tissue serum Stool (neonates)	PCR, culture FA, culture, PCR IgG antibody (differentiation between type 1 and type 2 requires special laboratory test) ¥ Culture
Measles (rubeola)	Serum Urine, blood, NP	IgM and IgG antibody culture
HAV	Serum	Anti-HAV IgM

CSF, Cerebrospinal fluid; EBV, Epstein-Barr virus; EEE, Eastern equine encephalitis; FA, fluorescent assay; HAV, hepatitis A virus; HSV, herpes simplex virus; Ig, immunoglobulin; NP, nasopharyngeal secretions; PCR, polymerase chain reaction; WEE, Western equine encephalitis.

Chapter 109: Infectious Syndromes in the Pediatric Intensive Care Unit

1. Which of the following should receive prophylaxis for a patient who presents with suspected meningococcal disease?

A. The physician who took over care 2 days after presentation

B. The unit clerk

C. The initial emergency room doctor who intubated the patient

D. The nurse in emergency room triage who saw the patient through a window

Preferred response: C

Rationale

Meningococcal disease can rapidly cause shock and multiorgan failure. Hence, prevention is the most important component in managing this severe illness. Only close contacts that were potentially exposed to nasopharyngeal secretions early in the treatment course are recommended to receive antibiotic prophylaxis.

Aggressive therapy for meningococcal disease has been shown to significantly improve outcomes. Early antibiotics, appropriate hemodynamic support, and referral to higher levels of care are all fundamental components of the management of invasive meningococcal infections.

2. A patient in Tennessee presents with a nonspecific rash and a headache, with some abdominal pain and myalgias. In addition to supportive treatment, which of the following specific therapies should be urgently initiated?

A. Corticosteroids for refractory shock

B. Doxycycline for consideration of Rocky Mountain spotted fever

C. Intravenous immunoglobulin for consideration of toxic shock syndrome

D. Ribavirin for hantavirus

Preferred response: B

Rationale

In patients presenting with nonspecific symptoms of fever, rash, and headache in endemic areas, the urgent consideration of Rocky Mountain spotted fever (RMSF) must be made. Doxycycline is the treatment of choice for this infection, and treatment should be initiated as early as possible upon suspicion. Other possible treatments include chloramphenicol, although doxycycline is the treatment of choice in all age groups.

Although toxic shock is on the differential for children with fever, rash, and shock, further testing can be performed before the urgent administration of intravenous immunoglobulin (IVIG). At this stage, there is no role for corticosteroid administration. Hantavirus is extremely rare in the southeastern United States.

3. A 7-year-old boy with a history of diabetes experiences acute pain, erythema, and intense swelling of the lower extremity that worsens over a 3-day period. The lesions progress to form skin vesicles and bullae with a bluish hue, and hypotension and acute respiratory distress syndrome (ARDS) develop. Which of the following pathogens is the most probable cause of this child's illness?

A. Group A β-hemolytic *Streptococcus* (GABHS)

B. *Neisseria meningitides*

C. *Staphylococcus aureus*

D. *Streptococcus pneumoniae*
Preferred response: A

Rationale

This diabetic child experienced a skin infection followed by signs of shock and ARDS, in addition to vesicles and bluish bullae suggestive of necrotizing fasciitis. This presentation points to the diagnosis of streptococcal toxic shock syndrome. GABHS causes toxic shock syndrome (TSS) that is more commonly associated with bacteremia and underlying soft tissue infection compared with staphylococcal TSS. Necrotizing fasciitis is characterized by extensive local necrosis of soft tissue and skin. GABHS TSS is associated with necrotizing fasciitis in 50% of cases. Apart from these two entities, invasive GABHS can present with more localized infections such as meningitis, pneumonia, osteomyelitis, septic arthritis, and surgical wound infections. It is important to note that severe GABHS rarely occurs following isolated pharyngitis; rather, most infections reflect the skin or soft tissue as the portal of entry.

With TSS, most cases present initially with nonspecific flulike symptoms that include fever, chills, and myalgias. In half of the patients, hypotension develops within the first 4 hours. Multiorgan failure, including ARDS and acute renal failure, occurs in up to 55% of patients. With fasciitis, pain is the most common initial symptom, usually without correlating physical signs. It is usually an acute process with rapid progression. The legs are the most common site, but the abdominal wall, groin, and perianal areas also are frequently affected. Approximately 80% of infants eventually have obvious signs of soft tissue infection, and of these infections, 70% develop into deeper infections requiring surgical debridement. Initially over 24 to 48 hours, the area becomes erythematous and swollen without sharp margins. Skin vesicles and bullae may be bluish and may appear by day 4 to 5, heralding fasciitis.

Invasive GABHS should be suspected, especially when a risk factor such as varicella or diabetes mellitus is present.

Staphylococcal TSS presents as fever, rash, hypotension, multiorgan involvement, and desquamation with specific criteria. Onset usually is abrupt, with fever, chills, malaise, and diffuse macular erythroderma. Fever often is remarkably high and resistant, occurring with intense myalgias, vomiting, and diarrhea. The rash is typically a generalized erythematous, deep-red “sunburn” and can be accompanied by conjunctival erythema. Within 24 hours, cardiovascular depression becomes prominent, with hypotension and decreasing systemic perfusion leading to severe shock and multiorgan dysfunction.

With regard to invasive disease in the critical care setting, pneumococcus most commonly presents as bacteremia, pneumonia, arthritis, and meningitis.

Most invasive meningococcal infections present as meningitis, whereas approximately 10% present as sepsis alone and approximately 40% present as both systemic and central nervous system disease. Invasive disease can be complicated by an immune-mediated arthritis, pancarditis, endophthalmitis, pneumonia, and adrenal insufficiency from Waterhouse-Friderichsen syndrome.

4. What is the most common late manifestation of Lyme disease in the pediatric population?

A. Arthritis

B. Carditis

C. Cerebellar ataxia

D. Seventh nerve facial palsies

Preferred response: A

Rationale

The clinical manifestations of Lyme disease are divided into three stages: early localized, early disseminated, and late disease. The early localized manifestations include the erythema migrans rash with central clearing. Stage 2 follows after a few weeks, with multiple smaller erythema migrans lesions and frank arthritis in up to 80% of cases. Neurologic symptoms (eg, meningitis, encephalitis, pseudotumor cerebri, cerebellar ataxia, and focal neuropathies, particularly seventh nerve facial palsies and optic nerve deficits) will develop in 15% of untreated patients. Approximately 5% of patients experience acute block of varying degrees but also myocarditis and dilated cardiomyopathy. Carditis from Lyme disease is rare in children and is usually transient. Arthritis of the knee and hip is the most common late presentation of Lyme disease, especially in children. In stage 3, late manifestations of damage to major organ systems may persist, particularly to joints and the neurologic system.

5. Which of the following manifestations of Lyme disease does not resolve with treatment?

   A. Arthritis

   B. Carditis

   C. Cerebellar ataxia

   D. Seventh nerve facial palsies

   Preferred response: D

Rationale

The drug of choice for early, localized disease in children older than 8 years is doxycycline, 100 mg twice daily. The American Academy of Pediatrics also recommends amoxicillin, 50 mg/kg/day for younger children. Treatment with antibiotics is recommended for 14 to 21 days. For early disseminated disease with mild migrans, isolated facial palsies, or mild arthritis, the same oral regimens are warranted. Some evidence shows that only 10 to 14 days of treatment may be sufficient. Treatment at the erythema migrans stage almost always prevents the development of later stages of the disease. Although the rash subsides within days, other symptoms may take several weeks before resolving. Treatment does not affect the resolution of nerve palsies but prevents the late disease.

6. A 6-year-old child who was bitten by a tick 7 days ago experiences fever, headache, and a petechial rash on his wrists and ankles. The rash has spread to his palms, soles, and trunk. Which of the following is the preferred choice of antibiotics for this patient?

   A. Amoxicillin

B. Chloramphenicol

C. Ciprofloxacin

D. Doxycycline

Preferred response: D

Rationale

Rocky Mountain spotted fever (RMSF) is a tick-borne bacterial infection resulting in a diffuse small-vessel vasculitis with the potential for causing multisystem disease. Initial symptoms often are nonspecific, with malaise and myalgias. The fever is observed in two-thirds of patients by day 3. Other common presenting symptoms are nausea, vomiting, and abdominal pain, especially in younger children. The rash often begins by day 4, with blanching maculopapules classically starting at the wrists and ankles and then appearing on the palms, soles, and trunk. Later, in up to 50% of patients, the rash may become petechial, purpuric, or even gangrenous. In younger patients the rash tends to develop earlier. Importantly, the absence of the pathognomonic rash does not exclude RMSF; an estimated 10% of cases are spotless. Headache is present in almost all adults and in most older children. Encephalitis, focal neurologic deficits, and meningismus have been described in some patients.

Empiric therapy is essential early in the course of illness because fatal outcomes have been linked to missed or delayed diagnosis and treatment. The drug of choice for treatment of RMSF is doxycycline. Until recently, chloramphenicol was recommended by the American Academy of Pediatrics and Centers for Disease Control and Prevention for children younger than 9 years because of the risk of teeth staining with tetracycline usage. However, because of the risk of aplastic anemia and retrospective evidence of higher case/fatality rates with chloramphenicol, doxycycline now is the first-choice therapy even in young patients. In fact, the risk of staining is limited with a short course of therapy. The fluoroquinolones also have activity against rickettsiae but have not been well studied in humans.

Chapter 110: Hospital-Acquired Infection in the Pediatric Intensive Care Unit: Epidemiology and Control

---

1. The institution of policies to reduce hospital-acquired infection has been *least* effective in preventing which of the following in children?

A. Catheter-associated urinary tract infection (CA-UTI)

B. Central line–associated bloodstream infection (CLA-BSI)

C. Ventilator-associated pneumonia (VAP)

D. Ventriculostomy-related infections

Preferred response: A

Rationale

There have been fairly dramatic declines in the incidence of VAP and CLA-BSI with the introduction of bundles of care that have been shown in large studies to be effective at their prevention. Ventriculostomy-related infections are not common. Hospital-acquired sinusitis is a challenging diagnosis to make without consensus criteria.

The incidence of CA-UTI remains significant, as the only evidence-proved intervention is reducing indwelling catheter days. In some situations urinary catheters must remain in situ, as reflected by the persistent incidence of CA-UTI. New techniques such as coated catheters or antibiotic instillation have yet to prove effective.

2. Wearing a mask is extremely important in the prevention of which of the following diseases?

   A. Clostridium difficile-associated diarrhea

   B. Methicillin-resistant *Staphylococcus aureus*

   C. *Neisseria meningitides* after 24 hours of antibiotics

   D. Respiratory syncytial virus

   Preferred response: D

Rationale

Masks to prevent acquisition of disease via the airborne or droplet route are useful primarily for respiratory viruses such as RSV or influenza, as well as diseases that are potentially aerosolized such as measles, tuberculosis, and chickenpox. Diseases that require direct contact for transmission, such as MRSA, clostridium difficile–associated diarrhea, and norovirus infection do not formally need a mask for prevention if all other precautions are maintained. However, many infection control programs will insist that practitioners wear masks in these conditions to avoid inadvertently touching their face with gloved, contaminated hands while providing care. *Neisseria meningitides* does not need droplet precautions after appropriate antibiotic therapy has been administered.

3. A 4-year-old child requires placement of a short-term central venous catheter (CVC). To assist with prevention of a central line–associated bloodstream infection (CLA-BSI), the person inserting the catheter should do which of the following?

   A. Always use an antibiotic-coated central line.

   B. Follow maximal barrier precautions, including head-to-toe draping of the patient and donning of a cap, mask, sterile gown, and sterile gloves.

   C. Institute prophylactic antibiotics.

   D. Prepare the skin with an antiseptic agent followed by a saline solution rinse of the prepared site prior to insertion.

   Preferred response: B

Rationale

Successful programs to reduce the incidence of CLA-BSI have been reported; all use multimodal team-based systematic approaches in which combinations of effective preventive interventions are introduced into a care setting.

The central line bundle is a compilation of eight components broken into two separate bundles for insertion and maintenance. The insertion bundle components include hand hygiene, maximal barrier precautions, and skin antisepsis. Maximal barrier precautions for the person inserting the catheter entail strict compliance with hand hygiene and wearing a cap that covers all hair, a mask that covers the mouth and nose securely, a sterile gown, and sterile gloves. The patient is covered from head to toe with a sterile drape except for a small opening for the insertion site and to maintain the airway. Chlorhexidine skin antisepsis is recommended over other antiseptic agents. With regard to the optimal site for a line, practitioners are urged to consider what is best for the patient based on current and future needs, anatomic features, and the inserter's technical competence.

Other components of success include empowering nurses to enforce the use of a central line checklist that incorporates inclusion of all components of the insertion bundle and constraining practice by creating central line insertion kits or carts that include the required equipment needed to maintain asepsis (eg, offering only one antiseptic—chlorhexidine).

Antibiotic-impregnated CVCs are not recommended for routine use unless concerted efforts to implement a strategy fail to reduce a local institution's infection rates below benchmark levels. Antibiotic-impregnated CVCs may be considered in specific patient populations such as immunosuppressed patients requiring long-term CVC use, although their superiority over standard CVCs in this population has never been proved.

In addition to hand hygiene, the maintenance bundle to prevent CLA-BSI incorporates multimodal education and training programs, accessing the lumens aseptically (ie, scrubbing the hub), checking the entry site for inflammation regularly (at a minimum, with each dressing change), daily review of line necessity with removal if it is deemed unnecessary, and a dedicated total parenteral nutrition line.

4. A 2-month-old infant is admitted to the pediatric intensive care unit (PICU) with a history of fever and irritability leading to a decreased level of consciousness, a raised red rash, and increasing respiratory distress. To decrease the spread of infectious agents within the PICU and hospital, what is the most important priority for this patient upon admission?

   A. Acquisition of blood for culture and sensitivity

   B. Acquisition of cerebrospinal fluid for culture and sensitivity

   C. Broad-spectrum antibiotic prophylaxis of exposed health care workers

   D. Isolation with negative pressure

   Preferred response: D

Rationale

Isolating a patient in a negative-pressure room is the first step in preventing the spread and potential cross-contamination of unknown contaminants.

5. What is the most prevalent contagion in central line–associated bloodstream infection (CLA-BSI) in critically ill children with a central venous catheter?

   A. *Candida* species

   B. Coagulase-negative *Staphylococcus*

C. Enterobacteriaceae

D. *Pseudomonas* species

Preferred response: B

Rationale

The most common infecting organism in persons with CLA-BSI is the gram-positive bacteria coagulase-negative *Staphylococcus,* a group of about 20 species, including *Staphylococcus epidermidis,* which are normal flora of human skin. gram-negative bacteria, including Enterobacteriaceae, and nonfermenting gram-negative bacteria, such as *Pseudomonas* species, *Acinetobacter* species, and *Stenotrophomonas* species, account for about 25% of infections. Increasingly, *Candida* species infections are recognized.

6. A key principle for the elimination of ventilator-associated pneumonia (VAP) includes which of the following?

A. Institution of prophylactic antibiotics

B. Minimization of aspiration of secretions and colonization of the aerodigestive tract

C. Placement of the patient in the prone position

D. Regularly scheduled instillation and suctioning of the endotracheal tube

Preferred response: B

Rationale

Strategies of prevention are directed against the three mechanisms by which VAP is thought to occur: aspiration of secretions, colonization of the aerodigestive tract, and use of contaminated equipment. General recommended measures are to conduct active surveillance for VAP, minimize the duration of ventilation and use noninvasive ventilation whenever possible, perform daily assessments of the patient's readiness to be weaned from ventilation, and educate health care workers who care for ventilated patients about VAP.

Specific precautions of the pediatric VAP bundle are practicing hand hygiene before and after circuit manipulation, elevating the head of the bed (the angle varies depending on positioning limitations of the child based on his or her age), positioning the oral or nasal gastric tube properly, eliminating the routine use of instillation prior to suctioning of the endotracheal tube, changing in-line suctioning catheters only when they are visibly soiled or malfunctioning, providing regular oral care for all children, and maintaining the ventilator tubing in a dependent position.

7. Which of the following is the most important action staff can take to prevent a urinary tract infection (UTI) in patients in the PICU?

A. Catheterize all children with continuous morphine infusions.

B. Limit the use of urinary tract instrumentation.

C. Maintain adequate hand hygiene

D. Insert urinary catheters using an aseptic technique.

Preferred response: B

Rationale

Guidelines for the prevention of catheter-associated urinary tract infection (CA-UTI) in acute care hospitals focus on certain key strategies, all related to urinary catheter use: (1) recommendations regarding which patients should receive indwelling urinary catheters; (2) recommendations for catheter insertion; (3) recommendations for catheter maintenance; and (4) quality improvement programs to achieve appropriate placement, care, and removal of catheters. The most important action that PICU staff can take to prevent UTIs is to limit the use of urinary tract instrumentation, particularly indwelling urinary catheters. Systemic morphine infusions are not a contraindication to the removal of the urinary catheter.

Proper technique for catheter insertion includes hand hygiene before and after any manipulation of the device, use of aseptic technique, use of the smallest bore catheter needed, and proper securement of the catheter after insertion to prevent movement. The catheter should be maintained as a closed drainage system with unobstructed urine flow. The catheter and collecting system should be replaced if the system is disconnected or if leaks occur. Standard precautions should be used for any manipulation of the catheter or collecting system (eg, use of gloves and gowns as appropriate). Systemic antimicrobials, bladder irrigation with antimicrobial agents, and complex drainage systems with antiseptic agents are not recommended to prevent CA-UTI. Special catheter materials (eg, antimicrobial-impregnated catheters) are only recommended if a comprehensive strategy to reduce CA-UTI rates is unsuccessful.

8. Standard precautions of infection control include hand hygiene, safe injection practices, use of personal protective equipment where appropriate, and appropriate respiratory hygiene and cough etiquette. Hand hygiene has been identified as a simple yet effective step in drastically reducing health care–associated infections. What is true regarding hand hygiene?

   A. It is not necessary if donning surgical gloves.

   B. It is limited to patient contact only.

   C. It is most effective when using soap and water.

   D. It is recommended before touching a patient, before performing clean/aseptic procedures, after body fluid exposure/risk, after touching a patient, and after touching a patient's surroundings.

   Preferred response: D

Rationale

The World Health Organization Patient Safety initiative on hand hygiene emphasizes five moments for hand hygiene: before touching a patient, before performing clean/aseptic procedures, after body fluid exposure/risk, after touching a patient, and after touching a patient's surroundings.

Chapter 111: Sepsis

---

1. Which one of the following forms of shock best describes the hemodynamic

alterations seen in patients with septic shock?

A. Cardiogenic shock

B. Hypovolemic shock

C. Obstructive shock

D. Variable combinations of cardiogenic, hypovolemic, and distributive forms of shock

Preferred response: D

Rationale

Shock states can be grouped into four broad categories: hypovolemic, cardiogenic, obstructive, and distributive shock. Septic shock is unique because all four forms of shock may be involved simultaneously. The patient may have hypovolemic shock resulting from capillary leak, increased insensible water losses, poor intake, or decreased effective blood volume secondary to venodilation and arterial dilation (ie, increased vascular capacitance). Cardiogenic shock manifests as depressed myocardial contractility and low cardiac output secondary to myocardial-depressant effects of bacterial toxins and inflammatory cytokines. Obstructive shock can result indirectly from diffuse microvascular thrombosis or directly from abdominal compartment syndrome. Distributive shock can result directly from abnormally low systemic vascular resistance, leading to maldistribution of blood flow, or can result indirectly from the inability of tissues to adequately use oxygen at the mitochondrial level (ie, cytopathic hypoxia).

The degree to which an individual patient manifests these physiologic perturbations is highly variable. In some cases, patients display increased cardiac output with diminished systemic vascular resistance. The presenting symptoms in this type of patient are tachycardia, a hyperdynamic precordium, bounding pulses, and warm, flushed skin characteristic of the distributive mode of shock or the so-called warm shock state. Despite this clinical appearance, the perfusion of major organs during warm shock may remain highly compromised secondary to maldistribution of blood flow. Alternatively, a patient with depressed cardiac output and elevated systemic vascular resistance has cool, mottled skin with diminished pulses and poor capillary refill characteristic of the cold shock state. Limited data and our collective anecdotal experience suggest this latter presentation, cold shock, is more common in younger children compared to teenagers and adults. It has been suggested that patients who develop community-acquired septic shock more commonly present to the ICU with signs of cold shock, whereas patients who develop septic shock secondary to catheter-related infections more commonly present to the ICU with signs of warm shock. It is important to recognize that a given patient may transition from one shock state to another, and recognition and reassessment of these classes of shock are absolutely central to the choice of cardiovascular medications.

2. Which of the following provides the best rationale for prescribing hydrocortisone in patients with septic shock?

A. As an antiinflammatory agent

B. As an immune modulating agent

C. To compensate for relative adrenal insufficiency

D. To improve cardiac output

Preferred response: C

Rationale

Because immune/inflammatory dysregulation is a well-accepted pathophysiologic concept in septic shock, there has been a great deal of effort in developing treatment strategies directly targeted at immune/inflammatory modulation. Steroids have long been proposed as a general antiinflammatory strategy. In many clinical settings, patients with septic shock demonstrate worsening of their shock temporally associated with antibiotic administration. It is thought this phenomenon results from a massive release of bacterial toxins after antibiotic-mediated bacterial killing and a subsequent inappropriately exuberant immune/inflammatory response. However, the use of high-dose steroids to blunt this response is now universally accepted to be of no benefit and potentially harmful.

A more recent approach to using steroids in septic shock involves the concept of relative adrenal insufficiency and an association between relative adrenal insufficiency and catecholamine refractory shock. A landmark study by Annane and colleagues demonstrated a substantial benefit in adults with septic shock having "relative adrenal insufficiency" (based on cortisol levels and ACTH stimulation testing) and treated with replacement hydrocortisone. However, a subsequent trial did not demonstrate the efficacy of hydrocortisone replacement, thus leading to an ongoing, unresolved controversy in the field. Further, Boonen and colleagues reported a reduction in cortisol metabolism related to suppressed expression and activity of cortisol-metabolizing enzymes during adult critical illness, thereby adding another confounding variable when considering administration of corticosteroids for septic shock.

Conflicting data and controversy also exist in the pediatric septic shock population, and existing data are currently limited to meta-analyses, observational studies, and practitioner anecdotes and experience. A retrospective analysis of an existing transcriptomic database of pediatric septic shock demonstrated that the administration of corticosteroids in pediatric septic shock was associated with the repression of genes corresponding to adaptive immunity, raising questions about potential harm associated with corticosteroid administration during septic shock. Jardine and colleagues examined genes involved in cortisol synthesis, metabolism, and activity in critically ill pediatric patients using the tag single nucleotide polymorphism (SNP) methodology. They identified an SNP in the *MC2R* gene (which codes for the ACTH receptor) and demonstrated that the AA genotype was associated with a low free cortisol response to critical illness. One report described the development and validation of a real-time subclassification method for septic shock using previously identified gene expression-based subclasses, which corresponded to genes for adaptive immunity and glucocorticoid receptor signaling. The study reported that allocation to the subclass with decreased expression of the glucocorticoid receptor signaling pathway genes was independently associated with increased mortality, and adjunctive corticosteroid administration to patients in that subclass was independently associated with almost four times the risk of mortality.

It is possible that patients with septic shock and high levels of illness severity stand to benefit the most from adjunctive corticosteroids. Funk and colleagues stratified a large cohort of adults with septic shock into quartiles of illness severity using APACHE II scores. Corticosteroid administration was associated with decreased mortality for patients in the highest quartile of illness severity. In contrast, when a large cohort of children with septic shock was stratified for baseline mortality risk using stratification biomarkers, corticosteroids were not associated with decreased mortality for patients in the intermediate or high baseline mortality risk groups.

The role of hydrocortisone replacement in pediatric septic shock represents another major challenge in the field that must be directly addressed by a large, multicenter, randomized trial. Current barriers to conducting this important trial include lack of equipoise in the pediatric critical care community, lack of consensus regarding the definition of relative adrenal insufficiency, and our inability to select which patients with septic shock are most likely to benefit from adjunctive corticosteroids. Thus at present, treatment guidelines suggest that hydrocortisone replacement therapy be considered for patients who appear refractory to resuscitative measures, have a known history of adrenal insufficiency, have already received exogenous steroids, or have an abnormal ACTH stimulation test result. Given the lack of objective evidence supporting the efficacy of adjunctive corticosteroids, and accumulating evidence suggesting harm, the otherwise strong recommendation for corticosteroids in the current pediatric guidelines should be revised accordingly.

Chapter 112: Multiple Organ Dysfunction/Failure Syndrome in Children

---

1. A patient has a new onset three-organ failure with a reduction in platelet count to less than 100,000/uL, an elevated LDH, and renal dysfunction. According to these criteria, what multiple organ failure (MOF) phenotype does this patient have?
   A. Immune paralysis/lymphoid depletion syndrome
   B. Secondary hemochromatosis–associated hepatopancreatic MOF
   C. Sequential MOF
   D. Thrombocytopenia-associated MOF (TAMOF)
   Preferred response: D

Rationale

TAMOF represents a thrombotic microangiopathy syndrome (TMA) mediated by microvascular thrombosis that can range from fibrin-mediated disseminated intravascular coagulation (DIC) to vWF multimer mediated secondary TMA/thrombotic thrombocytopenic purpura. These patients commonly have reduced ADAMTS 13 activity that can respond to intensive plasma exchange with

resolution of organ dysfunction. The MOF phenotypes are not mutually exclusive.

2. A patient with multiple organ failure (MOF) develops nosocomial infections with gram-negative bacteria and fungus and also has viral reactivation. This patient most likely has which MOF phenotype?

   A. Hyperleukocytosis-associated MOF

   B. Immune paralysis/lymphoid depletion

   C. Sequential MOF

   D. Thrombocytopenia-associated MOF (TAMOF)

   Preferred response: B

Rationale

This patient most likely has immune paralysis. This is a syndrome marked by a profound Th2 response. Whole blood ex vivo TNF-α production is markedly reduced (<200 pg/mL) for greater than 3 days in these patients. In the authors' center, patients with three-organ failure and a TNF-α response <160 pg/mL all developed secondary infection. Immune paralysis can be caused when apoptotic lymphocytes are phagocytized by monocytes/macrophages. These patients commonly have an absolute lymphocyte count <1000/μL for greater than 3 days. At autopsy these patients have lymphoid depletion. Immune paralysis can be reversed by holding immune suppressants. Subcutaneous low-dose GM-CSF can reverse immune paralysis and nosocomial infection risk in patients not receiving immune suppressants.

3. A patient is admitted to the ICU with acute respiratory distress syndrome (ARDS) and is mechanically ventilated. Over time the child develops an increasing alanine aminotransferase (ALT) and now meets criteria for liver and renal dysfunction. What multiple organ failure (MOF) phenotype does this patient most likely have?

   A. Hyperleukocytosis associated MOF

   B. Immune paralysis/lymphoid depletion

   C. Sequential MOF

   D. Thrombocytopenia-associated MOF (TAMOF)

   Preferred response: C

Rationale

This child has sequential MOF that is commonly associated with viral/lymphoproliferative disease. High levels of sFasL can cause liver injury in this population. In transplant patients Epstein-Barr virus (EBV) viral IL-10 DNA intercalates into B cells, causing proliferation. Holding immune suppressants, and subsequent treatment with B-cell monoclonal antibody rituximab, is the preferred treatment. In nontransplant patients with a family history of similar disease, X-linked immune-proliferative disease or another form of primary hemophagocytic lymphohistiocytosis (HLH) is likely. These patients have absent NK cell/CTL cell activity due to a variety of known defects in perforin signaling. These children are unable to kill viruses or cancer cells. They are also unable to induce activated immune cell death. The treatment is chemotherapy to stop immune proliferation

followed by bone marrow transplantation to restore NK/CTL cell function. For children with rheumatologic disease with arthralgia, serositis, and skin rash, the process is mediated by reduced T regulatory cell function leading to uncontrolled inflammation. These patients respond to pulse steroids or anakinra.

4. A patient has hepatobiliary dysfunction and disseminated intravascular coagulation with a ferritin level >500 pg/L. What multiple organ failure (MOF) phenotype is this patient most likely to have?
   A. Hyperleukocytosis-associated MOF
   B. Immune paralysis/lymphoid depletion
   C. Macrophage activation syndrome
   D. Thrombocytopenia-associated MOF (TAMOF)
   Preferred response: C

Rationale

Macrophage activation syndrome is the common end pathway of uncontrolled inflammation. Begin by eradicating the source (dead or alive). Concomitantly consider the use of methylprednisone, IVIG, plasma exchange, tocilizumab or anakinra to quell inflammation until the infectious/necrotic source is removed and host metabolism is restored.

Chapter 113: Bites and Stings

---

1. A 4-year-old girl was playing in the park when her mother heard her screaming and running away. The child had accidentally disturbed a honeybee nest while climbing a tree. Which of the following is considered a lethal dose of honeybee stings?
   A. 200 to 800 stings or 10 stings/kg
   B. 300 to 1000 stings or 25 stings/kg
   C. 500 to 1200 stings or 20 stings/kg
   D. 1000 to 1500 stings or 25 stings/kg
   Preferred response: C

Rationale

A lethal dose of honeybee stings is estimated at 500 to 1200 total stings or 20 stings/kg. Serious envenomation can result from as few as 50 stings. Sting removal should be done as quickly as possible, regardless of the method of removal. A delay of a second or two (to find a knife or credit card) results in a higher dose of venom injected. Grasping the stinger does not increase the venom dose.

2. A 7-year-old boy was on a camping trip with his Boy Scout troop when a snake lunged from the bushes and bit him on the leg. He felt immediate pain in his right leg and started to have difficulty breathing. The boy was transported to the nearest hospital for further evaluation and treatment. You are the on-call wilderness medicine physician and arrive to the patient's room. His vital signs are

BP, 140/80 mm Hg; HR, 135 bpm; RR, 24; and his oxygen saturation as measured by pulse oximetry is 100% without supplemental oxygen. He is writhing in pain and feels very uncomfortable. After your initial assessment of ABCs and controlling his pain with fentanyl, which of the following accurately describes antivenin administration?

A. A mandatory skin test is recommended for CroFab prior to administration.

B. One vial of CroFab every 6 hours is recommended for maintenance therapy.

C. Pediatric dosing of CroFab is not the same as adult dosing.

D. The starting dose of CroFab is 4 to 6 vials and is increased to 8 to 12 vials in patients with severe symptoms.

Preferred response: D

Rationale

Pediatric dosing of antivenin is the same as adult dosing and depends on the species of snake as well as the clinical manifestations. A starting dose is 4 to 6 vials, which is increased to 8 to 12 vials in patients who have immediate life-threatening venom effects. Each vial should be mixed with 18 mL of NS, reducing the overall dissolution time when compared to being mixed with sterile water. It is no longer recommended to skin test antivenin prior to its administration. Two vials of CroFab should be given every 6 hours for antivenin maintenance.

3. A patient's mother calls the pediatric intensive care unit saying a rattlesnake has just bitten her child. What is the best advice for her?

A. Call 9-1-1.

B. Immerse the bitten extremity in ice.

C. Perform an incision at the site of the bite and suck out the blood.

D. Place a tourniquet.

Preferred response: A

Rationale

The factors that most effectively reduce snakebite-related injury and death in the United States are rapid transport, intensive care, and the administration of antivenom. All patients with snakebites should be transported to the hospital as expeditiously and safely as possible, preferably through a 9-1-1 call (where available). The following measures are not recommended for first aid: incision, suction, use of tourniquets, use of electric shock, placing ice directly on the wound, use of alcohol, or use of folk therapies. Insufficient evidence exists for splinting or positioning (eg, above or below the level of the heart). Therefore the extremity initially should be maintained in a neutral position of comfort.

Chapter 114: Heat Injury

---

1. Which of the following statements is correct regarding the regulation of body temperature?

A. Antipyretics are crucial in the treatment of heat stroke due to their action in normalizing the elevated hypothalamic set point.

B. Application of water immersion in a heat stroke patient is mainly via radiation.

C. Evaporation is mediated parasympathetically.

D. When ambient temperature equals body temperature, body cooling is mainly via convection.

Preferred response: C

Rationale

Heat dissipation occurs via four mechanisms: (1) conduction to the adjacent air and objects, (2) convection through air or liquid, (3) radiation of heat energy, and (4) evaporation. Once activated by the hypothalamus, the efferent heat response is both autonomic and behavioral. Blood delivery to the body surface is increased by sympathetic discharge causing cutaneous vasodilatation. Blood flow may increase eight- to sixteen-fold, up to 8 L/min. Thermal sweating, in response to parasympathetic discharge, can produce approximately 1 $L/h/m^2$ of body surface sweat. Secondary to cutaneous vasodilatation and sweating, blood is shunted toward the periphery, and visceral perfusion is reduced, especially to the liver, kidneys, and intestines. Rising core temperature will also lead to tachycardia, a high cardiac output state, and an increase in minute ventilation. When ambient temperature equals or exceeds body temperature, conduction, convection, and radiation cease to be effective. Losses of salt and water through sweating may lead to dehydration and salt depletion, resulting in impaired thermoregulation. A combination of high ambient humidity and temperature creates a particularly dangerous situation. With ambient humidity of 90% to 95%, evaporation of sweat essentially stops, and if ambient temperature reaches body temperature, the body can no longer eliminate heat.

A variety of cooling methods have been used to promote heat loss, and controversy continues regarding the best cooling technique. Cold/ice water immersion—a cooling method based on conduction—was twice as rapid in reducing the core temperature as the evaporative spray method in patients with exertional heat stroke. The mechanism for this rapid cooling relates to the high thermal gradient between the skin and ice water, leading to a faster heat loss by conductance as compared with evaporation. Ice water is readily available, does not require special equipment, and is suitable for both classic and exertional heat stroke. Although some authors regard ice water immersion to be the most efficient cooling method, others claim there is no evidence to support the superiority of any cooling technique, especially in classic heat stroke.

Antipyretics are not recommended for treatment of heat stroke. These drugs lower body temperature by normalizing the elevated hypothalamic set point. In heat stroke, the elevated body temperature reflects a failure of the cooling mechanism rather than an abnormal set point.

2. Which of the following statements is correct regarding the treatment of heat stroke?

A. Dantrolene has a key role in the treatment of heat stroke.

B. Induced hypothermia has been proved to improve neurologic outcome in

exertional heat stroke.

C. Patients with heat stroke may continue to deteriorate even after body temperature normalizes.

D. The target temperature of active cooling is 37°C.

Preferred response: C

Rationale

Heat stress initiates cellular acute phase responses aimed at protecting against injury and promoting tissue repair. A variety of cytokines are produced in response to heat stress. Plasma levels of both proinflammatory and antiinflammatory cytokines are elevated in patients with heat stroke. Soluble TNF, IL-2, and IL-6 receptors are also elevated in heat stroke. It has been shown that the severity of symptoms during heat stroke correlates well with IL-1 and IL-6 levels. Progression from heat stress to heat stroke depends on the time and extent of exposure to severe environmental conditions, but the acute phase response may continue after the patient is cooled. Onset of inflammation may be local with systemic progression, involving endothelial cell activation, release of endothelial vasoactive factors, endothelial cell injury, and microvascular thrombosis.

Heat stroke is a systemic disorder. Per definition, core temperature must exceed 40°C, and the patient exhibits hypovolemic shock and central nervous system abnormalities such as delirium, convulsions, or coma.

After the airway is secured, the child with heat stroke should be moved to a cool environment. Clothes should be removed, intravenous access should be obtained, and a normal saline or lactated Ringer solution bolus should be administered. Fluid resuscitation, besides ensuring organ perfusion, increases heat dissipation and lowers core temperature by improving skin blood flow. Cooling should be started as early as possible with readily available methods. Prompt and appropriate (<39°C) cooling within 30 minutes yields survival rates of 90% to 100% in cases of exertional heat stroke and 40% to 85% in classic heat stroke. The rule of "cool first, transport second" applies. This recommendation does not discount the potential for outstanding care at the hospital but rather prioritizes appropriate care in the first 30 minutes after collapse, which is critical for survival.

A variety of cooling methods have been used to promote heat loss, and controversy continues regarding the best cooling technique. Cold/ice water immersion—a cooling method based on conduction—was twice as rapid in reducing the core temperature as the evaporative spray method in patients with exertional heat stroke.

Antipyretics are not recommended for treatment of heat stroke. These drugs lower body temperature by normalizing the elevated hypothalamic set point. In heat stroke, the elevated body temperature reflects a failure of the cooling mechanism rather than an abnormal set point. Acetaminophen and salicylates should be avoided due to their potential to aggravate coagulopathy and hepatic injury. Dantrolene has been used successfully for malignant hyperthermia and neuroleptic malignant syndrome. There are conflicting data regarding its effectiveness in heat stroke. Once a core body temperature of 39°C has been achieved, active cooling may be stopped. This end point appears to be safe in terms of mortality. Patients with heat stroke may continue to deteriorate even after body temperature is normalized because of the

inflammatory response.

3. For any patient who presents with a heat-related illness, it is critical to lower the core body temperature below which of the following?
   A. 41°C (105.8°F)
   B. 38.9°C (102°F)
   C. 39.5°C (103.1°F)
   D. 40.5°C (104.9°F)
   Preferred response: B

Rationale

The treatment of heat stroke starts at the scene with removing the patient from the circumstances that led to heat stroke to prevent any further increase in core temperature. Rapid cooling and maintenance of organ system perfusion and function are the two major goals. Adherence to the basic resuscitative guidelines is required, with protection of the airway, management of breathing, monitoring for hypovolemia/shock, and appropriate fluid resuscitation. The most severely affected children have altered mental status, rising body temperature, and hypovolemic shock. After the airway is secured, a child with heat stroke should be moved to a cool environment; his or her clothes should be removed; intravenous access should be obtained with one or two large-bore catheters; and a normal saline solution or Ringer lactate solution bolus of 20 mL/kg should be administered. Fluid resuscitation, besides ensuring organ perfusion, increases heat dissipation and lowers core temperature by improving skin blood flow. Cooling should be started as early as possible with whatever method is available, and the patient should be transported to the nearest hospital appropriate for children. Decreasing body temperature below 38.9°C within 30 minutes of presentation has been shown to improve survival.

Chapter 115: Accidental Hypothermia

---

1. Decisions about transport of victims and hospital management of hypothermia victims are influenced by temperature measurements. Which of the following statements is correct regarding the diagnosis of accidental hypothermia?
   A. Bladder and rectal temperature correlate well with core temperature during rewarming of patients with severe hypothermia.
   B. Core temperature in the lower third of the esophagus correlates well with heart temperature.
   C. Standard oral or axillary measurements do not provide accurate estimates of core temperature.
   D. Tympanic thermometers are well suited for low temperature readings in the field.
   Preferred response: B

Rationale

Bladder and rectal temperatures may lag behind core temperature during rapid changes in temperature. The mean difference between pulmonary artery and rectal temperature measured 0.8°C in one study. The core temperature in the lower third of the esophagus correlates well with heart temperature. Oral and axilla measurements with standard thermometers are not accurate in hypothermic patients.

Research has shown a large difference at low ambient temperature between epitympanic measurements, using the thermistor-based technique, and esophageal measurements. The difference can be reduced by insulating the ear. Thermometers based on infrared technique do not seal the ear canal and are not designed for temperature readings in winter conditions.

2. Selection of hypothermia victims for extracorporeal rewarming and prognostication can be challenging. Which of the following statements about triage and neuroimaging studies is correct?
   - A. Core temperature at the time of cannulation for rewarming has no prognostic value for survival.
   - B. Computerized axial tomography scans (CT scans) obtained after successful resuscitation of hypothermia victims frequently reveal attenuation of the gray matter (blurring of the gray-white interface).
   - C. Resuscitative efforts should be terminated in victims with severe hyperkalemia (>8 mmol/L) and acidosis (pH <6.6) on admission.
   - D. Survival goes hand in hand with the duration of cardiac arrest, the duration of CPR, and the time to ECMO/CBP.

   Preferred response: A

Rationale

Core temperature on admission does not have a clear association with likelihood of survival. The victims in the Præstø Fjord boating accident had CT scans performed during the initial hospitalization and 6 months later. All were normal. Extremely high potassium values (>10 mmol/L) have been associated with poor outcome, and a value >12 mmol/L on admission is probably a reason to terminate resuscitation of victims with severe hypothermia. Acidosis is often extreme, and pH values down to 6 have been reported in survivors. There is no clear correlation between survival and duration of cardiac arrest, duration of CPR, or time to ECMO/CBP.

3. Which of the following electrolyte abnormalities is more commonly due to renal injury during the rewarming phase of a patient with severe hypothermia?
   - A. Hyponatremia
   - B. Hypokalemia
   - C. Hypophosphatemia
   - D. Hyperkalemia

   Preferred response: D

Rationale

Renal injury may occur either because of hypothermia or during the rewarming process. The mechanisms involved in cold diuresis may include peripheral vasoconstriction and blunted response to antidiuretic hormone. Renal vasoconstriction and ischemia to the kidney may lead to oliguria and acute tubular necrosis in persons with severe hypothermia. Progressive hypokalemia develops during hypothermia, probably because of the shifting of potassium from the extracellular to the intracellular compartment, and significant hyperkalemia may develop during rewarming. Metabolic and respiratory acidoses are not uncommon findings in patients who have moderate and severe hypothermia.

4. Which of the following statements is correct regarding the pathophysiology of cold injury?

   A. At 29°C, the electroencephalogram is compatible with brain death.

   B. Cerebral blood flow decreases 6% to 7% for every 1°C decrease in temperature.

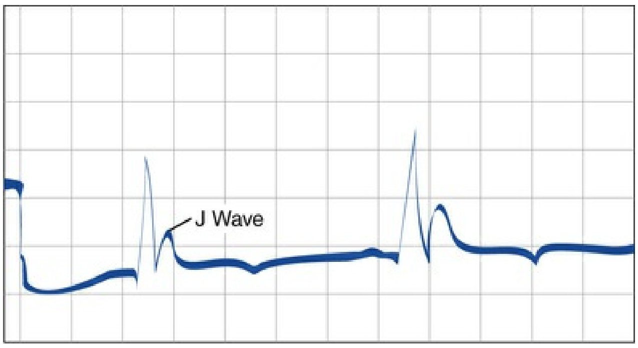
   C. Initial cardiovascular responses are arrhythmias and decreased cardiac output.

   D. Osborne or J waves on the electrocardiogram are pathognomonic for hypothermia.

   Preferred response: B

Rationale

The initial cardiovascular responses to hypothermia are vasoconstriction, tachycardia, and increased cardiac output. Further hypothermia results in decreased pacemaker and conduction velocity, causing bradycardia, heart block, and prolongation of PR, QRS, and QT intervals. Bradycardia becomes severe by 32°C. The myocardium becomes irritable and arrhythmias are common when core temperature reaches 30°C. The electrocardiogram may show a characteristic J or Osborne wave following the QRS complex (Fig. Q115.4). The presence of this wave is not pathognomonic for hypothermia and has no prognostic implications.



Cerebral oxygen consumption decreases in proportion to the reduction in metabolism that occurs with hypothermia. Cerebral blood flow decreases 6% to 7% for each 1°C decrease in temperature. Mild hypothermia may be associated with confusion, dysarthria, and impaired judgment. Deep tendon reflexes are depressed at a core temperature below 32°C because of slowed peripheral nerve conduction. As their body temperature drops, many patients no longer complain about being cold. Shivering thermogenesis ceases at 31°C. Pupillary responses decline and dilated

nonreactive pupils may be noted at temperatures below 30°C. Patients may experience hallucinations and sometimes paradoxically remove their clothes. The electroencephalogram shows abnormal activity at temperatures less than 32°C, and at 20°C the electroencephalogram may appear consistent with brain death.

5. Which of the following statements is correct regarding treatment of cold injury?
   A. Chest compressions in the pulseless patient should be initiated after rewarming has begun.
   B. Defibrillation that has failed after three successive attempts should be reattempted after core temperature is ≥30°C.
   C. Endotracheal intubation should not be attempted in the hypothermic patient due to risk of cervical spine injury as well as ventricular irritability during the procedure.
   D. The hypothermic heart has an exaggerated response to cardioactive drugs.
   Preferred response: B

Rationale

Chest compressions should be started immediately if the patient is pulseless with no detectable signs of circulation and may have to be continued for hours before extracorporeal rewarming can be started. Victims in cardiac arrest have survived when resuscitation after rescue was delayed by as much as 70 minutes. The advantages of endotracheal intubation outweigh the minimal risk of triggering ventricular fibrillation with the procedure. If cervical spine injury is suspected, the neutral position must be maintained with manual cervical stabilization. Care should be taken not to overventilate the patient's lungs because this can increase ventricular irritability. Defibrillation can be tried up to three times for ventricular tachycardia or fibrillation. If arrhythmia is resistant to three shocks in a patient with deep hypothermia, then further defibrillation attempts should be deferred until core temperature is ≥30°C. However, a systematic review of animal models performing resuscitation from ventricular fibrillation in severe hypothermia revealed much higher ROSC rates in studies administrating vasopressor medications. The hypothermic heart may also have a reduced response to pacing and cardioactive medications, but evidence for medication efficacy and risk of accumulation to toxic levels if administered repeatedly is limited and based mainly on animal studies.

Chapter 116: Drowning

---

1. A 3-year-old boy is rescued after being submerged for approximately 15 minutes in an icy lake. Upon arrival of EMS personal, he is pulseless and his core body temperature is 20°C. According to basic life support algorithms, his airway is cleared, and bag-valve mask ventilation and chest compressions are initiated. After 5 minutes in the emergency department, spontaneous circulation has returned, and his core body temperature is 32°C. Which of the following is the most appropriate initial method of managing his temperature?
   A. Active forced air surface rewarming to achieve immediate normothermia

B. Cardiopulmonary bypass with a warmed circuit to achieve immediate normothermia

C. Passive rewarming no more than 0.5°C/hr

D. Surface cooling to achieve therapeutic hypothermia of 28 to 32°C for 72 hours

Preferred response: C

Rationale

The protective effect of cold water temperature on drowning victims is uncertain. Therapeutic hypothermia for out-of-hospital pediatric cardiac arrest victims has been shown to be of no benefit. Hypothermia can have adverse effects on the cardiac rhythm. However, rapid rewarming in children with brain injury is detrimental. Aggressive measures to achieve immediate normothermia are therefore not recommended. Thus passive rewarming of no more than 0.5°C per hour is a good approach in this case, in which return of spontaneous circulation has been achieved.

2. An 18-month-old boy was found face down in the family's aboveground swimming pool. After initial stabilization measures in the emergency department, the child is intubated on mechanical ventilation on moderate settings. He has normal hemodynamics and is not on inotropes or vasoactive medications. Despite not receiving sedation, he is currently comatose. Pupils are 5 mm and sluggishly reactive bilaterally. He has brisk reflexes throughout. Upon painful stimulation, he does not open his eyes and exhibits flexor posturing of upper extremities. Of the following, which is the best management strategy to improve outcome?

A. Maintaining a oxyhemoglobin saturation greater than 93%

B. Mannitol 0.5 g/kg every 6 hours

C. Mild hyperventilation keeping Pa_{CO_2} 35 to 40 mm Hg

D. Therapeutic hypothermia of 32 to 34°C for 72 hours

Preferred response: A

Rationale

The patient has early signs of hypoxic-ischemic encephalopathy after a drowning accident. The treatment should focus on mitigating secondary brain injury by ensuring an adequate supply of oxygen and nutrients to the brain. This consists mainly of supportive care of hemodynamics, oxygenation, and ventilation. Thus maintaining oxyhemoglobin saturation greater than 93% in this patient, whose hemodynamic status is adequate, is the best strategy. Therapeutic hypothermia, goal-directed intracranial pressure monitoring, hyperventilation, and osmotherapy are all unproved therapies in drowning and pediatric cardiac arrest, and they can have adverse effects.

3. In victims of drowning, aspiration of seawater compared with freshwater may result in which of the following?

A. Hyperelectrolytemia

B. Hypervolemia

C. Hyponatremia

D. More disruption of surfactant

Preferred response: A

Rationale

Freshwater, which is considerably hypotonic compared with plasma, is rapidly absorbed across the alveoli into the circulation. Aspiration of large amounts of freshwater may cause increased blood volume and hemodilution, resulting in hypoelectrolytemia and hemolysis. The osmolarity of seawater is three to four times greater than that of plasma. The presence of seawater in the lung draws water from the circulation into the alveoli with the potential for hemoconcentration, hyperelectrolytemia, and decreased blood volume. The extent to which these changes occur, however, depends on the amount of aspirated fluid.

Although the differences between changes in electrolytes and blood volume after saltwater and freshwater aspiration have been emphasized in the past, they are of little clinical significance in patients who survive long enough to be transported to a medical facility.

4. A 10-year-old child is recovered from the bottom of a chlorinated pool, resuscitated at the scene, and taken to your pediatric intensive care unit. He is endotracheally intubated, sedated, and placed on the conventional ventilator. Settings are as follows: pressure control ventilation with peak inspiratory pressure, 25 cm H_2O; positive end-expiratory pressure (PEEP), 6 cm H_2O; pressure support, 10 cm H_2O above PEEP, rate 18 breaths/min; and fraction of inspired oxygen (FiO_2), 0.50. His saturations are 90%. A chest radiograph taken on admission reveals pulmonary edema. Your next best course of action is to do which of the following?

A. Administer furosemide intravenously.

B. Increase the tidal volume to 12 mL/kg.

C. Increase the PEEP.

D. Increase the FiO_2.

Preferred response: C

Rationale

Freshwater aspiration results in marked disruption of the surfactant system of the lung, resulting in alveolar instability and atelectasis. Pulmonary abnormalities in both freshwater and saltwater aspiration include pronounced injury to the alveoli and pulmonary capillaries, resulting in increased membrane permeability, exudation of proteinaceous material in alveoli, pulmonary edema, decreased lung compliance, and increased airway resistance. The extent of these abnormalities may not be manifested fully for several hours after the submersion episode and may be progressive in nature. Acute respiratory distress syndrome (ARDS) is the hallmark of delayed pulmonary insufficiency resulting from aspiration in drowning and is sometimes referred to as *secondary drowning.* Lung compliance is reduced, necessitating higher inflation pressure to maintain adequate tidal volume (V_T).

Low V_T at low functional residual capacity (FRC) leads to a vicious cycle of

atelectasis, decreased compliance, and further reduction in V_T. The critical opening pressure necessary to begin alveolar inflation is increased. Appropriate PEEP needs to be administered to maintain the necessary FRC for adequate oxygenation and ventilation above the critical opening pressure. Salutary effects of PEEP are from maintaining alveolar stability and alveolar recruitment and increasing FRC. It stabilizes the relatively softer chest wall of a child, thus minimizing chest wall recoil and further decrease in FRC. Because PEEP also displaces intravascular water into interstitial and perilymphatic spaces, the results are decreased venous admixture and improved compliance.

Airway resistance is relatively less affected or only minimally elevated unless the airway is obstructed by aspirated debris. The time constant, a product of compliance and resistance, reflects the time needed for pressure equilibration between the proximal airway and alveoli to occur. In patients with ARDS, the time constant is decreased, allowing for quicker approximation of pressures at these sites during the inspiratory and expiratory phases of mechanical ventilation. A relatively large V_T (10 to 12 mL/kg) is associated with greater ventilator-induced lung injury in patients with ARDS, whereas smaller V_T (6 mL/kg) is associated with less volutrauma.

Most drowning victims are intravascularly hypovolemic regardless of the type of aspiration because of excessive capillary permeability resulting from asphyxia and the loss of protein-rich fluid into the alveoli. Administering diuretics in this scenario would not benefit the patient. The child's pulse oximeter reading is 90% despite the pulmonary edema. There is no need to increase the FiO_2 in this case.

5. Which of the following is more likely to have a positive effect on outcome in drowning victims?

   A. Adequate resuscitative efforts at the scene

   B. Length of submersion

   C. Moderate hypothermia at the scene

   D. pH on admission over 7.1

   Preferred response: A

Rationale

The outcome of drowning victims depends largely on the success of resuscitative measures taken at the scene of the injury. Patients who are successfully resuscitated and who are conscious on arrival at a hospital have an excellent chance of intact survival. With improved ventilatory techniques and aggressive management, pulmonary injury can be successfully managed in most patients. For persons who continue to require resuscitation in the emergency department, a variety of prognostic factors have been evaluated. Variables such as age, length of submersion, serum pH, and body temperature, although previously thought to influence outcome, have not been shown to be reliable prognostic indicators. In addition, it has been suggested that the absence of cognitive function 72 hours after the hypoxic event is strongly associated with either death or survival in a persistent vegetative state. The need for continued cardiopulmonary resuscitation at the hospital, cardiopulmonary resuscitation greater than 25 minutes, fixed and dilated pupils, seizures, flaccidity, a Glasgow Coma Scale score of 5 or less, and decreased cerebral

blood flow are of poor prognostic significance in the absence of hypothermia. Severe hypothermia has been shown to influence the outcome favorably even after prolonged submersion; however, not all hypothermic drowning victims are fortunate enough to escape serious neuronal damage.

6. A 3-year-old boy is admitted to the ICU after being rescued from drowning in a neighbor's swimming pool 1 hour ago. He was found unconscious and cyanotic. He received mouth-to-mouth resuscitation at the poolside. When EMS arrived, he was crying and coughing frequently. In the ICU, he was appropriately responsive to the environment. His vital signs were as follows: respiratory rate, 40/min; heart rate, 110/min; blood pressure, 108/74 mm Hg; and temperature, 36.5°C (rectal). Chest auscultation revealed bilateral wheezes. Pulse oximetry showed 89% oxygen saturation in room air and 100% with supplemental oxygen. A chest x-ray showed a few streaky infiltrates in the perihilar region. Eight hours after admission, he was found to have increasing respiratory distress with audible grunting and intercostal retractions. His vital signs now show the following: respiratory rate, 50/minute; heart rate, 130/minute; blood pressure, 110/60 mm Hg; and temperature, 38.5°C (rectal). Results of an arterial blood gas study show the following: pH, 7.34; P_{CO_2}, 38 mm Hg; and P_{O_2}, 54 mm Hg on supplemental oxygen. A repeat chest x-ray shows bilateral whiteout. The patient is electively intubated and mechanically ventilated. Which of the following is the most likely explanation for his pulmonary dysfunction?

   A. Bacterial infection from contaminated water

   B. Increased pulmonary capillary permeability

   C. Increased sympathetic nervous system activity

   D. Pulmonary edema from fluid overload

   Preferred response: B

Rationale

Clinically, pulmonary abnormalities are encountered in both freshwater and seawater aspiration. These abnormalities are consistent with pronounced injury to alveoli and pulmonary capillaries resulting in increased membrane permeability, exudation of proteinaceous material in alveoli, pulmonary edema, decreased lung compliance, and increased airway resistance. The extent of these abnormalities may not be manifested fully for several hours after the submersion episode and may be progressive in nature. ARDS is the hallmark of delayed pulmonary insufficiency resulting from aspiration in drowning and is characterized by progression of the alveolar-capillary block, increased capillary permeability, and pulmonary edema. Reduced FRC and diffusion barrier resulting from an accumulation of fluid and inflammatory cells in the alveoli and interstitium further accentuate hypoxemia.

Chapter 117: Burn and Inhalation Injuries

1. A 4-year-old child was playing alone in the garage and was found after spilling hydrofluoric acid on her bilateral upper extremities. En route to the hospital, intravenous access was obtained. Upon arrival in the emergency room, the patient is noted to have sustained 15% total body surface area burns that appear to be partial thickness. What is the initial step of management of this burn?

   A. Administer a 1-liter bolus of 0.9% saline intravenously.

   B. Immediately dress the burn and start resuscitation based on the Parkland formula.

   C. Neutralize the hydrofluoric acid with calcium.

   D. No resuscitation is necessary and the patient can be discharged.

   Preferred response: C

Rationale

The patient sustained a hydrofluoric acid burn that should immediately be neutralized and irrigated in order to halt any further liquefactive necrosis. According to the American Burn Association, the patient should be admitted based on her age, the percentage of total body surface area burn, and the type of burn the patient sustained. Bolus therapy is not indicated in the resuscitation of burn patients due to the increased risks of morbidity and mortality related to pulmonary edema and massive fluid shifts.

2. After being rescued from a trailer explosion, a 10-year-old boy is transported to the hospital. He sustained 45% total body surface area flame burn, centrally located on his torso, abdomen, face, and upper extremities. He arrived in respiratory distress with noticeable carbonaceous sputum and soot in his oropharynx. He is immediately intubated and a bronchoscopy is performed in the intensive care unit. After the patient is connected to the ventilator, what is the next step in management?

   A. Administer oxygen with FiO_2 of 0.5 and titrate based on pulse oximeter values.

   B. Administer nebulized heparin.

   C. Administer oxygen with FiO_2 of 1.0 and check a carboxyhemoglobin level and arterial blood gas.

   D. Perform a computed tomography of the chest.

   Preferred response: C

Rationale

The patient displayed the classic signs and symptoms of inhalational injury. After undergoing intubation, it is vital to increase the FiO_2 to 1.0 in order to rapidly decrease the carboxyhemoglobin level to less than 10% and decrease acidosis. Treatment of inhalational injuries consists of supportive care, ventilator support, airway clearance, and the addition of therapeutic adjuncts.

3. Which of the following hormones is decreased during the ebb phase after burn injury?

   A. Aldosterone

B. Cortisol

C. Growth hormone

D. Insulin

Preferred response: D

Rationale

Burn injuries are associated with severe alterations in metabolism and enhanced neuroendocrine responses that exceed those reported for any other illness or injury. These alterations were first described by Cuthbertson as occurring in two distinct periods: the *ebb phase,* encompassing the first 24 hours, and a subsequent *flow phase,* which may last several days.

The ebb phase begins with the sensory signal to the brain that tissue injury has occurred and the consequent release of corticotropin and antidiuretic hormone in response to pain, fear, hypoxia, and hypovolemia. This phase is dominated by α-adrenergic receptor stimulation and catecholamine secretion and is characterized by a redistribution of blood flow from skin to vital organs. Plasma cortisol, aldosterone, and growth hormone levels are markedly elevated, and insulin secretion is curtailed. Hyperglycemia resulting from increased sympathetic activity, secretion of epinephrine, inhibition of insulin release, and cortisol and glucagon release is common in adults, but hypoglycemia is frequently observed in children. The child's reduced glycogen stores and proportionally higher basal energy expenditures may explain the different responses in serum glucose.

The flow phase generally begins 24 hours after injury, lasts several days, and is characterized by hypermetabolism, increased cardiac output, and increased oxygen consumption. Accelerated tissue catabolism, increased urinary nitrogen losses, and altered glucose metabolism are invariably present. The degree of hypermetabolism generally correlates with the extent of the injury and is associated with a moderate increase in body temperature.

4. The best way to assess the severity of carbon monoxide (CO) injury is through which of the following?

A. Blood carboxyhemoglobin (HbCO) levels

B. Clinical symptomatology

C. PaO_2

D. Pulse oximetry saturations

Preferred response: B

Rationale

CO is responsible for up to 80% of inhalation fatalities. It has approximately 250 times greater affinity for the hemoglobin iron than does oxygen. This affinity is so strong that breathing 0.1% inspired CO (normal level: 0.001%) generates greater than 60% HbCO. With prolonged exposure, CO also can bind to other proteins, notably mitochondrial cytochrome oxidase and myoglobin, interfering with cellular oxygen utilization and energy production.

The displacement of oxygen from hemoglobin diminishes the oxygen-carrying

capacity of the blood, shifts the oxyhemoglobin dissociation curve to the left, and induces tissue hypoxia and metabolic acidosis. As the fraction of dissolved oxygen and PaO_2 remain normal, arterial blood gases do not reflect the degree of cellular hypoxia. The pulse oximeter is similarly fooled by the presence of hemoglobin saturated with CO, dropping only 1% for each 10% HbCO present. Because calculated oxygen saturations do not reflect the presence of HbCO, direct measurements of both HbCO and oxyhemoglobin are necessary.

The severity of CO poisoning is proportional to the degree of induced hypoxia, which leads to cardiac and central nervous system dysfunction. Blood HbCO levels are only loosely correlated with the clinical condition of the patient and may be falsely correlated with the clinical condition of the patient and falsely lowered by oxygen administration before hospitalization. Extrapolation of HbCO levels to the time of rescue by the use of nomograms has greater prognostic value. Levels less than 20% are accompanied by minor symptoms of headache and irritability. Levels greater than 60% are frequently fatal. Studies in animals have shown that blood HbCO levels are not the only determining factor and that even when extrapolations to zero time are possible, the outcome cannot be accurately predicted.

5. A child who has been in a house fire is admitted to your pediatric intensive care unit. He sustained second- and third-degree burns to 40% of his body surface and first-degree burns to 10% of his body surface. His body surface area is 0.8 m^2. What are his total fluid requirements for the first day?

   A. 2400 mL

   B. 3200 mL

   C. 4200 mL

   D. 5000 mL

   Preferred response: B

Rationale

When analyzing the extent of injury, you should consider only second- and third-degree burns. In this case, the child has sustained second- and third-degree burns to 40% of his BSA, so his total burn surface area (TBSA) is 40% of 0.8 m^2, or 0.32 m^2. The total fluid requirements for the first day are calculated as follows:

$$2000\ \text{mL/m}^2\ \text{BSA} + 5000\ \text{mL/m}^2\ \text{TBSA}$$

In this case, (2000 mL × 0.8) + (5000 mL × 0.32) = 1600 + 1600 = 3200 mL.

Half should be given in the first 8 hours and the other half during the next 16 hours at a constant hourly rate.

6. This child remains in the PICU receiving topical antimicrobial therapy to prevent wound infection. On day 5 of admission, unexplained metabolic acidosis develops. You suspect it is due to use of which of the following topical antimicrobial agents?

   A. Silver nitrate

   B. Silver sulfadiazine

C. Cerium nitrate

D. Mafenide acetate

Preferred response: D

Rationale

Topical antimicrobial agents are routinely used in the treatment of burn wounds. Silver sulfadiazine is the topical agent of choice for burned patients because of its low toxicity and wide antimicrobial spectrum; 0.5% silver nitrate is also utilized but is not as popular because it stains bed clothing, equipment, and physical facilities and discolors the burn wounds, making them difficult to assess. Gentamicin or tobramycin cream is a suitable alternative for patients with superinfected wounds or allergies to sulfa preparations.

Mafenide acetate has antimicrobial activity against gram-positive and gram-negative organisms but limited antifungal activity. Its use is limited by the fact that it is rapidly absorbed from the wounds and therapeutic wound concentrations are difficult to maintain. The drug is a strong carbonic anhydrase inhibitor, and metabolic acidosis commonly develops. Deaths from secondary pulmonary failure have been reported.

7. The half-life of HbCO in room air is approximately which of the following?

A. 1 hour

B. 2 to 3 hours

C. 4 to 6 hours

D. 8 to 12 hours

Preferred response: C

Rationale

Supplemental oxygen should be administered to all victims of fires. Inhaled oxygen immediately begins to displace CO from HbCO. The half-life of HbCO can be decreased from 4 to 6 hours in room air to 40 to 60 minutes while the patient is breathing 100% oxygen at high flows. Oxygen therapy should be continued until the concentration of HbCO is less than 15%, metabolic acidosis is corrected, and alterations in consciousness resolve.

8. Which of the following is the preferred management of the airway in patients who have sustained thermal injury to the upper airway?

A. Observation and intubation if respiratory distress develops

B. Early orotracheal intubation

C. Early nasotracheal intubation

D. Tracheostomy

Preferred response: C

Rationale

Thermal injury to the upper airway is best managed by elective early nasotracheal intubation. This is particularly true when patients have circumferential burns of the

neck or lips, intraoral burns, swelling, stridor, or vocal cord dysfunction. Oral endotracheal tubes, although easier to place initially, are difficult to maintain in position. Primary tracheostomies, especially through burn tissue, are associated with many complications and increased risk of sepsis. Their use should be restricted to patients in whom endotracheal intubation is impossible or those in whom timely extubation fails.

9. A 6-year-old boy who weighs 24 kg spills hot noodles on his abdomen and thighs, sustaining second- and third-degree burns on 25% of his TBSA. No intravenous therapy is initiated prior to arriving at the emergency department (ED) 1 hour after the injury. Vital signs in the ED include the following: heart rate, 140 beats per minute; blood pressure, 90/45 mm Hg; and respiratory rate, 30 per minute, with an oxygen saturation of 94% on room air. Initial resuscitation in this patient would include which of the following?

   A. 1-L bolus of 0.9% normal saline solution infused using a pressure bag

   B. 10 mL per kg of packed red blood cells

   C. 250 mL of 25% albumin followed by 5 L of crystalloid infused over 8 hours

   D. Lactated Ringer solution at 150 mL/h for the first 8 hours

   Preferred response: D

Rationale

The Parkland formula estimates initial burn resuscitation as 4 mL × % TBSA × weight (kg). Half of this estimation is given during the first 8 hours after burn injury, with the remainder given over the following 16 hours. Bolus fluid therapy is not indicated in the resuscitation of burn patients because of the increased risks of morbidity and mortality related to pulmonary edema and massive fluid shifts.

The timing and use of colloid in burn resuscitation is controversial. Evidence has shown that colloid resuscitation provides no long-term benefits, does not affect mortality, and is more expensive compared with crystalloid solutions. The theoretic reduction in complications and mortality with colloid use has not been demonstrated in human trials.

10. A 5-year-old boy is rescued from his second-story bedroom in the midst of a fire and transported to the hospital. Upon arrival at the ED, the patient is noted to have labored breathing, altered mental status, carbonaceous sputum, and soot in the oropharynx. He does not demonstrate evidence of cutaneous thermal injury. Which of the following is indicated next in this patient?

    A. Albuterol nebulizer treatment and 23-hour observation

    B. Bronchoscopy with early intubation

    C. Chest x-ray, arterial blood gas, and oxygen therapy via facemask

    D. Tracheostomy or cricothyroidotomy in the ED

    Preferred response: B

Rationale

The pediatric patient with signs and symptoms of inhalation injury (ie, mechanism of prolonged smoke exposure, carbonaceous sputum, and soot in the oropharynx)

requires early diagnosis with bronchoscopy and early intubation.

Chapter 118: Evaluation, Stabilization, and Initial Management After Multiple Trauma

1. What is the preferred method to obtain intravenous access in a hemodynamically unstable child?
   A. Intraosseous insertion of a needle into the marrow cavity of a long bone
   B. Multiple attempts at peripheral IV access
   C. Percutaneous placement of a central venous catheter into the internal jugular vein
   D. Venous cutdown in the groin or ankle
   Preferred response: A

Rationale

Peripheral intravenous access is the preferred vascular route. If peripheral intravenous access is unsuccessful after two attempts in a hemodynamically unstable child, intraosseous insertion into the marrow cavity should be performed. Intraosseous insertion is faster than a venous cutdown and safer than central venous catheter placement.

2. In progressive hypotension, a palpable pulse is lost *last* in which artery?
   A. Brachial
   B. Carotid
   C. Dorsalis pedis
   D. Radial
   Preferred response: B

Rationale

If only the carotid pulse is palpable, the systolic blood pressure (SBP) is 60 to 70 mm Hg. If the carotid and femoral pulses are palpable, the SBP is 70 to 80 mm Hg. If the radial pulse is palpable, the SBP is >80 mm Hg.

3. A 5-year-old boy was struck by an automobile going approximately 25 mph. Witnesses report he was unconscious at the scene. EMS intubated the child's trachea using rapid sequence intubation (RSI) for altered mental status. Additional prehospital care included placement of a cervical spine collar, placement of a single peripheral intravenous line in the child's left antecubital vein, and splinting of bilateral lower extremities for bilateral open lower extremity fractures. Which of the following choices are the most appropriate series of steps in the primary survey for this patient with multiple trauma injuries?

A. Assess for appropriate tube size and placement, auscultate breath sounds bilaterally, place a central line in an internal jugular vein, perform a pupillary examination and assign a Glasgow Coma Scale (GCS) score, expose the patient, and log-roll the patient maintaining cervical spine precautions.
B. Assess for appropriate tube size, auscultate breath sounds bilaterally, place monitoring devices for vital signs and pulse oximetry, gain additional peripheral vascular access, perform a pupillary examination and assign a GCS score, expose the patient, and log-roll the patient maintaining cervical spine precautions.
C. Reintubate with a laryngeal mask airway (LMA), auscultate breath sounds bilaterally, place monitoring devices for vital signs and pulse oximetry, gain additional peripheral vascular access, perform a pupillary examination and assign a GCS score, expose the patient, and log-roll the patient maintaining cervical spine precautions.
D. Assess for appropriate tube size, auscultate breath sounds bilaterally, place monitoring devices for vital signs and pulse oximetry, achieve intraosseous access, expose the patient, perform a pupillary examination and assign a GCS score, and perform a log-roll of the patient maintaining cervical spine precautions.

Preferred response: B

Rationale

This child's trachea was intubated outside the hospital, and assessment is required to ensure that the size and depth of the tube are appropriate. Auscultation of the chest to assess for bilateral breath sounds on the anterior chest and axilla is the next step. Placement of monitoring devices is performed in the primary survey and is usually done by the ancillary staff while the examining physician is performing airway and breathing assessment. The patient has a single peripheral access site; in a child with multiple traumatic injuries, two peripheral access sites are warranted, and an attempt should be made to establish a second site before gaining central access or intraosseous access. The assessment of disability in this patient with a GCS score may be difficult given that he underwent RSI. However, the scenario does not comment on the time that has elapsed since RSI medications were given, and the primary survey should be done the same way every time so that no injuries are missed.

Responses A and D are incorrect because in the circulation step, peripheral access should be attempted before attempts are made to gain either central or intraosseous access. In addition, central access is usually attempted in the femoral veins because the neck is blocked with a cervical spine collar.

Response C is incorrect because it states that the patient should be reintubated with an LMA. This action is incorrect because an established airway should not be removed before assessment, and an LMA is not considered a definitive airway.

4. A 7-year-old boy who is a restrained back seat passenger is involved in a high-speed motor vehicle crash with a fatality at the scene. He arrives at your level I pediatric trauma center by helicopter. EMS reports that the patient had loss of consciousness at the scene and gross deformity of the right leg. Initial vital signs

were as follows: heart rate, >150 beats per minute; blood pressure, 90/50 mm Hg; and respiratory rate, >30 per minute. The patient is lethargic and responds slowly to the examining physician. Examination shows absent peripheral pulses and a markedly prolonged capillary refill time. What is the calculated blood volume this patient has lost?

A. <10%

B. 10% to 20%

C. 20% to 30%

D. 30% to 45%

Preferred response: D

Rationale

(see Table Q118.4)

TABLE Q118.4

Systemic Responses to Blood Loss in Pediatric Patients

System	Mild Blood Volume Loss (<30%)	Moderate Blood Volume Loss (30%-45%)	Severe Blood Volume Loss (>45%)
Cardiovascular	Increased heart rate; weak, thready peripheral pulses; normal systolic blood pressure (80-90 + 2 × age in years); normal pulse pressure	Markedly increased heart rate; weak, thready central pulses; low normal systolic blood pressure (70-80 + 2 × age in years); narrowed pulse pressure	Tachycardia followed by bradycardia; very weak or absent peripheral pulses; hypotension (<70 + 2 × age in years); narrowed pulse pressure (or undetectable diastolic blood pressure)
Central nervous system	Anxious; irritable; confused	Lethargic; dulled response to pain[a]	Comatose
Skin	Cool, mottled; prolonged capillary refill	Cyanotic; markedly prolonged capillary refill	Pale and cold
Urinary output[b]	Low to very low	Minimal	None

[a]The child's dulled response to pain with this degree of blood loss (30%-45%) may be indicated by a decreased response to IV catheter insertion.

[b]After initial decompression by urinary catheter. Low normal is 2 mL/kg/hr (infant), 1.5 mL/kg/hr (younger child), 1 mL/kg/hr (older child), and 0.5 mL/hg/hr (adolescent). IV contrast can falsely elevate urinary output.

Data from Committee on Trauma, American College of Surgeons. Advanced Trauma Life Support for Doctors, Student Course Manual. 9th ed. Chicago: American College of Surgeons; 2012.

Chapter 119: Severe Traumatic Brain Injury in Infants and Children

1. Which of the following may contribute to the surprisingly poor outcomes seen in infants versus adolescents with severe traumatic brain injury (TBI)?

A. A lower propensity for neuronal apoptosis early in development

B. A lower propensity for reduced cerebral blood flow with hypotension in infants

C. Increased cerebral blood flow autoregulatory reserve in infants

D. The high incidence of inflicted childhood neurotrauma as the injury mechanism in infants

Preferred response: D

Rationale

The high incidences of inflicted childhood neurotrauma (shaken baby syndrome) as the injury mechanism in infants, as well as a higher propensity for neuronal apoptosis early in development and reduced cerebral blood flow autoregulatory reserve in infants, are believed to be critical to the well-characterized poor outcomes of infants and young children (particularly those younger than 4 years of age) after severe traumatic brain injury. Inflicted TBI outcomes are poor, likely related to many factors such as superimposed secondary hypoxemic insults, delay in presentation, multiple insults, and other factors. Propensity for delayed neuronal death from apoptosis is well characterized in developmental models of brain injury, although the exact age that this propensity decreases in humans remains somewhat unclear. Finally, studies, as described in this chapter, have demonstrated reduced autoregulatory reserve in infants and young children relative to older children, and thus hypotension can more readily contribute to secondary reductions in cerebral blood flow in infants after TBI.

2. Which of the following was suggested to be the most important complication of hypothermia in the pediatric randomized controlled trial (RCT) carried out by the Canadian Multicenter Clinical Trials Group?

A. Asystole

B. Cardiac arrhythmias

C. Hypotension during rewarming

D. Sepsis

Preferred response: C

Rationale

Remarkably, classical complications of hypothermia such as cardiac arrhythmias or sepsis have not been commonly described as occurring in the major clinical trials of mild hypothermia. These may have been more problematic in earlier eras when moderate levels of hypothermia for prolonged durations were commonly employed. In contrast, hypotension during rewarming appears to be common and importantly associated with an unfavorable outcome. This may relate to the aforementioned autoregulatory reserve in infants and young children, or other factors. In addition, in the field of cardiac arrest the development of subclinical seizures during rewarming has also been observed, as has toxicity from drugs that have accumulated during hypothermia. The timing and rate of rewarming could thus be extremely important. For example, rewarming during a period of intracranial hypertension could be highly deleterious.

3. Which of the following effectors is directly responsible for the cleavage of cytoskeletal proteins and inactivation of deoxyribonucleic acid (DNA) repair proteins in the cell death cascade following severe traumatic brain injury?

A. Calcium
B. Calcineurin
C. Caspase 3
D. Calpain
Preferred response: C

Rationale

Cells that die after traumatic brain injury (TBI) can be categorized on a morphologic continuum ranging from necrosis to apoptosis. Apoptosis is a morphologic description of cell death defined by cell shrinkage and nuclear condensation, internucleosomal DNA fragmentation, and the formation of apoptotic bodies. Apoptosis requires a cascade of intracellular events for completion of cell death; thus *programmed cell death* is the currently accepted term for the process that leads to apoptosis. In diseases with complex and multiple mechanisms, such as TBI, distinguishing apoptosis from necrosis may be difficult. Programmed cell death requires initiation via either intracellular or extracellular signals. Intracellular signaling appears to be initiated in mitochondria, triggered by disturbances in cellular homeostasis such as adenosine triphosphate depletion, oxidative stress, or calcium fluxes. Mitochondrial dysfunction leads to egress of cytochrome *c* into cytosol. Cytochrome *c* activates the initiator cysteine protease caspase-9. Caspase-9 then activates the effector cysteine protease caspase-3, which cleaves cytoskeletal proteins, DNA repair proteins, and activators of endonucleases. Extracellular signaling of apoptosis occurs through the tumor necrosis factor superfamily of cell surface death receptor (Fig. Q119.3).

4. An 11-year-old child who has been in a motor vehicle crash is admitted to the emergency department in a comatose state, with a Glasgow Coma Scale (GCS) score of 7. Motor response to noxious stimulus is decerebrate posturing. The head and cervical spinal computed tomography (CT) scans on admission were normal. Which of the following approaches is the best course of action for this child?
   A. Cervical immobilization, nasotracheal intubation, repeat head CT scan in 24 hours
   B. Cervical immobilization, orotracheal intubation, placement of intracranial pressure (ICP) monitor
   C. Nasotracheal intubation, placement of ICP monitor, repeat head CT scan in 24 hours
   D. Orotracheal intubation, repeat head CT scan in 24 hours

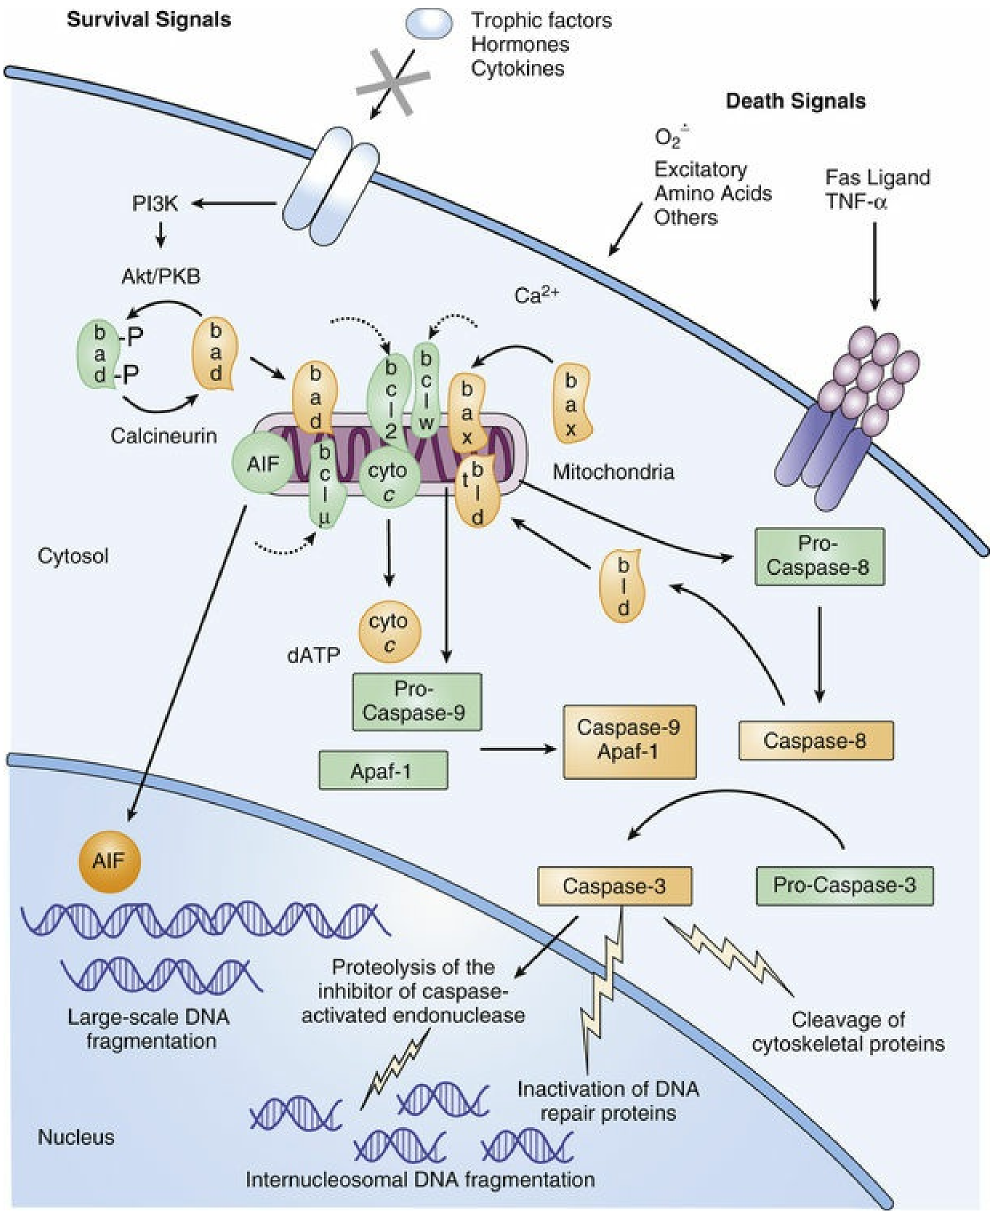


FIG. Q119.3

Preferred response: B

Rationale

The initial evaluation of a child after severe TBI begins by demonstrating the presence of a patent, maintainable airway—the patient must be conscious, alert, and breathing spontaneously. Unconscious patients must be assumed to have an obstructed airway requiring immediate evaluation. Tracheal intubation of the child with severe TBI requires use of a cerebroprotective, rapid-sequence technique when possible. Bag-valve-mask positive pressure ventilation should be avoided. However, in cases of hypoxemia or impending herniation, positive pressure ventilation should be instituted immediately. Because use of the bag-valve-mask technique may cause unintentional cervical spine (C-spine) manipulation, care is advised. If a victim of TBI meets any of the criteria listed in Box Q119.4, assisted ventilation is indicated. In children, the recommended route of initial airway control is orotracheal intubation

under direct vision. Nasotracheal intubation should be avoided. Blind passage of the endotracheal tube around the acute nasopharyngeal angle makes this procedure an unnecessary obstacle to rapid, physiologic resuscitation. Orotracheal intubation can be accomplished with use of a two-person strategy that protects the C-spine from injury. A normal lateral C-spine roentgenogram is reassuring but does not rule out C-spine injury. Spinal immobilization must be maintained and is accomplished via in-line cervical immobilization by one operator while the second intubates the trachea.

Box Q119.4

Criteria for Intubation of the Head-Injured Child

GCS score ≤10

Decrease in GCS of >3, independent of the initial GCS score

Anisocoria >1 mm

Cervical spine injury compromising ventilation

Apnea

Hypercarbia (Pa_{CO_2} >45 mm Hg)

Loss of pharyngeal reflex

Spontaneous hyperventilation causing Pa_{CO_2} <25 mm Hg

Unfortunately, clinical signs such as pupillary size and light response and papilledema fail as early indicators of intracranial hypertension. Although the most reliable clinical signs are those associated with herniation, the introduction of ICP monitoring devices has allowed detection of intracranial hypertension before such changes are observed. In the pediatric guidelines, ICP monitoring was suggested as appropriate in children with an abnormal admission head CT scan and an initial GCS score between 3 and 8. Also, ICP monitoring was suggested to be appropriate in adults with severe TBI and a normal head CT scan if hypotension or motor posturing complicated the clinical course. This modality is essential to implementation of a physiologically guided approach to management of cerebral perfusion pressure in the infant or child with severe TBI. ICP monitoring has not been studied in a randomized controlled trial to establish its efficacy in altering outcome after severe TBI in either adults or children. Since publication of the pediatric guidelines, however, several studies have contributed new insight. Forsyth and colleagues examined the United Kingdom multicenter database of more than 500 cases of pediatric TBI and reported that both ICP >20 mm Hg and lack of ICP monitoring were independently associated with death before discharge. Given that raised ICP correlates with poor outcome, a strong rationale exists for identifying and treating this problem.

5. Which of the following options is considered second-tier therapy in the

management of traumatic brain injury?

A. Hypertonic saline solution

B. Mannitol

C. Mild hypothermia

D. Ventricular cerebrospinal fluid drainage

Preferred response: C

Rationale

Refractory intracranial hypertension occurs in 20% to 40% of cases of severe pediatric TBI and is associated with mortality rates of 30% to 100%. Several second-tier therapies are available for treatment of refractory intracranial hypertension (Fig. Q119.5). Second-tier therapies include barbiturates, hyperventilation, hypothermia, decompressive craniectomy, and lumbar cerebrospinal fluid drainage. First-tier therapies include ventricular cerebrospinal fluid drainage, osmolar therapy, sedation and neuromuscular blockade, and head elevation and midline position.

6. A 10-year-old child who has had a traumatic head injury is admitted to the pediatric intensive care unit with a GCS score of 8. The child has decerebrate posturing and only opens his eyes in response to noxious stimulus. What do you expect this child's verbal response to be at this time?

A. Confused

B. Inappropriate words

C. Incomprehensible sounds

D. Oriented

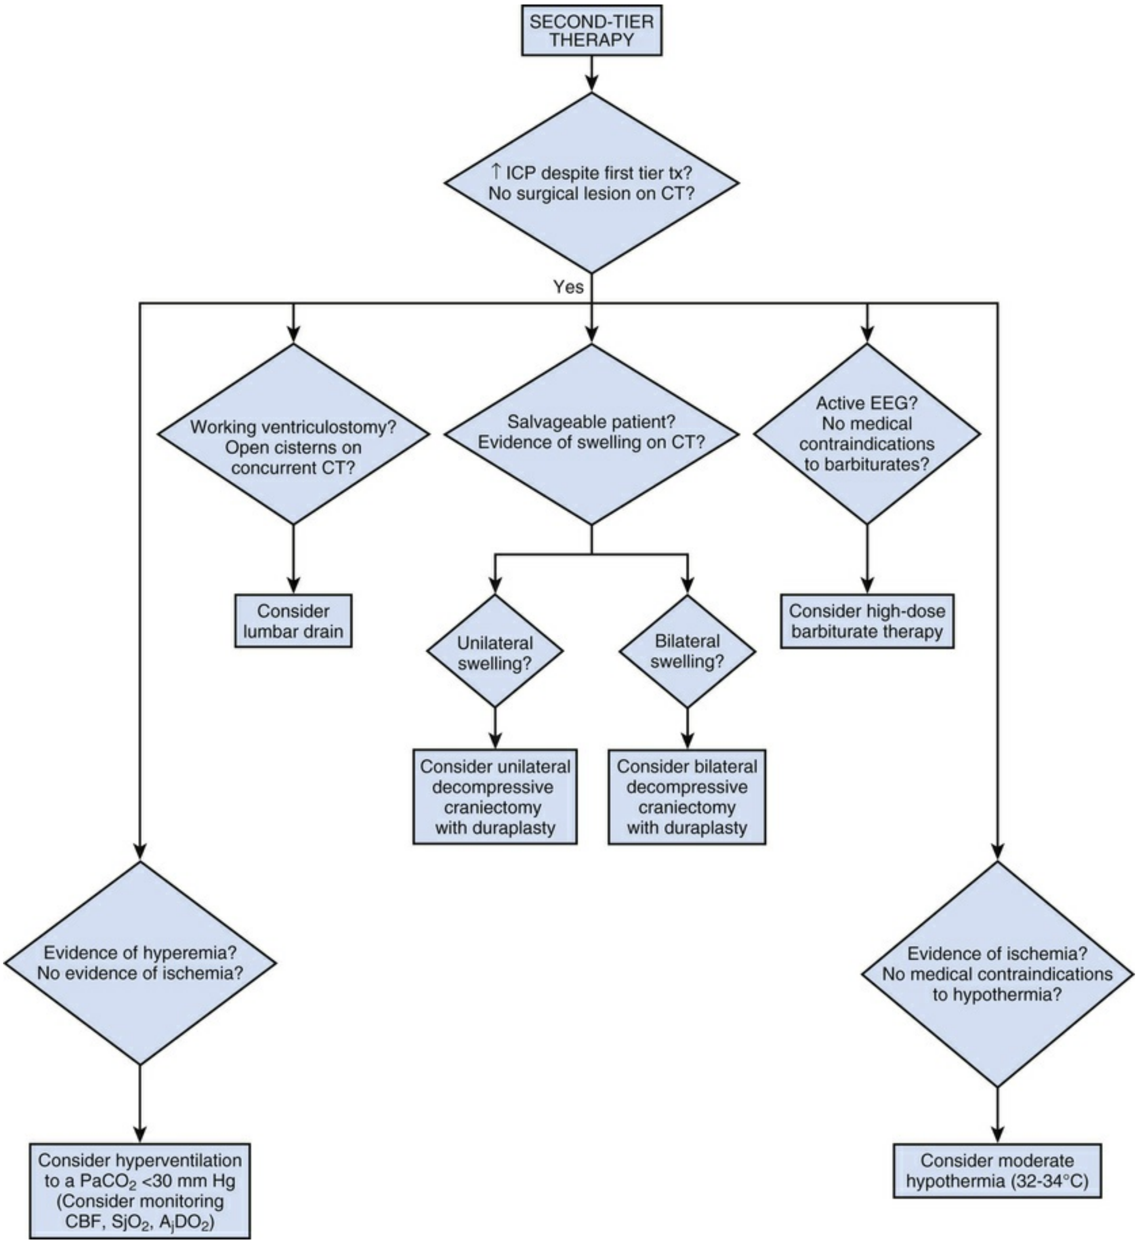

FIG. Q119.5

Preferred response: A

Rationale

This child's GCS score is 8. He has decerebrate posturing (motor score of 2) and opens his eyes to noxious stimuli (eye opening score of 2). His verbal score is 4, so he is confused (Table Q119.6).

TABLE Q119.6

Coma Scales

Glasgow Coma Scale	Modified Coma Scale	Point Scale
Eye Opening		
Spontaneous	Spontaneous	4
To speech	To speech	3

To pain	To pain	2
None	None	1
Verbal		
Oriented	Coos, babbles	5
Confused	Irritable	4
Inappropriate words	Cries to pain	3
Grunting	Moans to pain	2
None	None	1
Motor		
Follows commands	Normal spontaneous movements	6
Localizes pain	Withdraws to touch	5
Withdraws to pain	Withdraws to pain	4
Abnormal flexion	Abnormal flexion	3
Abnormal extension	Abnormal extension	2
Flaccid	Flaccid	1

Chapter 120: Thoracic Injuries in Children

1. For children sustaining traumatic injury to the chest, which of the following radiologic studies will most often be the only study required?
   A. Chest computed tomography with contrast
   B. Chest radiograph
   C. Magnetic resonance imaging of the chest
   D. Ultrasound
   Preferred response: B

Rationale

Chest radiograph is to be used as the initial screening tool in thoracic trauma. The routine use of computed tomography (CT) scanning is not justified unless there is adequate symptomatology to suggest significant injury, and unnecessary radiation should be avoided in children. The sensitivity of ultrasound for trauma in the pediatric population is low. Magnetic resonance imaging is costly and time consuming in the trauma setting.

2. Which of the following statements is true regarding physiologic considerations in children?
   A. Children are more likely to sustain rib fractures, due to their small size.
   B. Children are less likely to become hypoxic because of their high metabolic rate.
   C. Children can compensate and maintain a normal blood pressure with up to a 40% blood loss.
   D. Children have a greater capacity to maintain body heat, compared to adults.
   Preferred response: C

Rationale

The thoracic organs in a child exhibit different physiologic characteristics than do those of an adult. Increased cartilage content and incomplete ossification of the ribs make the thoracic cage more compliant than that of an adult, permitting the anterior ribs to be compressed against the posterior ribs. This compliance results in more kinetic energy being transmitted to intrathoracic organs without bony injury. Therefore pulmonary contusions without concomitant rib fractures are more common in children than in adults. Rib fractures and flail segments become more common as ossification occurs. The flail segment responds to changes in intrathoracic pressure rather than to the pull of respiratory muscles, resulting in retraction with inspiration and bulging with expiration. This paradoxical movement results in inefficient thoracic expansion and increased energy expenditure. Hypoventilation and subsequent atelectasis results from associated pain.

Children are more likely to become hypoxic due to their high metabolic rate and greater oxygen consumption. They have a high body surface to volume ratio, allowing for a higher rate of radiant cooling, leading to rapid hypothermia. A smaller chest transmits breath sounds more readily. Even in the presence of a large pneumothorax or effusion, breath sounds may seem equal.

Cardiac output in children is determined by heart rate and stroke volume. Contractility is largely fixed in early life. Children may compensate

hemodynamically and maintain a normal blood pressure with up to a 40% blood loss. Additionally, the less complete fixation of the mediastinum in children allows more visceral shift, greater compromise of preload, and profound hypotension.

3. What is the treatment for commotio cordis in children?
   A. Automated external defibrillator
   B. β-blockade
   C. Cardiac catheterization
   D. Precordial thump
   Preferred response: A

Rationale

Commotio cordis is a survivable phenomenon. The identification of ventricular tachyarrhythmias at the scene and in the emergency department resulted in shockable rhythms with survival due to the availability and use of an automated external defibrillator.

4. Which of the following findings on a chest x-ray is the *least* useful clue for traumatic aortic or great vessel injury in a young child?
   A. Blurring of the aortic knob
   B. Deviation of the nasogastric tube or central venous lines
   C. Rightward tracheal deviation
   D. Transverse mediastinal width and mediastinal width/chest width ratio
   Preferred response: D

Rationale

The findings of a chest x-ray examination of a young child with an acute intrathoracic vascular injury include a widened mediastinum, deviation of the nasogastric tube or central venous lines, blurring of the aortic knob, an abnormal paraspinous stripe, a rightward tracheal deviation, or an upward shift of the left main stem bronchus. Transverse mediastinal width/chest width ratios on supine chest films have been suggested as useful tools for identifying patients with possible traumatic aortic rupture. However, their clinical usefulness is limited by considerable overlap between normal and abnormal measurements, as is seen in infants with an enlarged thymus. This overlap has prompted other investigators to suggest that subjective assessment of anatomic mediastinal abnormality is more reliable in determining the need for aortography.

Chapter 121: Abdominal Trauma in Pediatric Critical Care

---

1. Which of the following injuries mandates a laparotomy?
   A. Extraperitoneal bladder rupture

B. Grade II splenic hematoma

C. Grade II hepatic hematoma

D. Intraperitoneal bladder rupture

Preferred response: D

Rationale

Intraperitoneal bladder rupture requires laparotomy because the urine will continue to extravasate into the peritoneal cavity causing sepsis and increased BUN/creatinine. A laparotomy will allow the surgeon to close the laceration. Extraperitoneal bladder injuries have been shown to heal with simple catheter drainage of the bladder, so these injuries do not require laparotomy.

2. Outside of laparotomy, what is the best diagnostic modality to identify the specific nature and extent of blunt intraabdominal injury?

A. Computed tomography

B. Diagnostic peritoneal lavage

C. Diagnostic laparoscopy

D. Focused abdominal sonography for trauma

Preferred response: A

Rationale

A CT scan is the only imaging modality listed to provide organ-specific information as to the location and extent of injuries in the abdomen.

3. What criterion is most important in determining the need for operative intervention after splenic laceration from blunt trauma?

A. Failure of angiographic embolization

B. Grade III or higher on computed tomography

C. Hemodynamic instability

D. Hemoglobin level less than 9 g/dL on presentation

Preferred response: C

Rationale

The majority of solid organ injuries after blunt trauma can be managed nonoperatively. Preservation of the spleen to maintain immune function is particularly important in young children. The most important criterion in determining if operative intervention is necessary is hemodynamic instability. Embolization may be attempted in stable patients with contrast blush on computed tomography. Laboratory values are less important in determining the need for laparotomy than is hemodynamic status, and hemoglobin levels as low as 7 g/dL are tolerable in stable children.

4. What definitive treatment is indicated for transection of the middle of the pancreas?

A. Early distal pancreatectomy

B. Endoscopic retrograde cholangiopancreatography

C. Nonoperative management

D. Percutaneous drainage

Preferred response: A

Rationale

Minor pancreatic injuries without duct compromise can be managed nonoperatively. Endoscopic retrograde cholangiopancreatography is useful to diagnose ductal transaction and can be used to place a stent across the injured duct and reduce the incidence of pseudocyst. Infected fluid collections require urgent percutaneous drainage. If a pseudocyst develops after pancreatic injury, delayed internal drainage might be necessary after allowing the pseudocyst wall to develop. When the pancreas has been transected at the neck or tail, the best results are obtained through early distal pancreatectomy.

Chapter 122: Child Abuse

---

1. A 28-month-old boy was brought to the emergency room with complaints of slipping and falling down the stairs while visiting his dad. The parents were in the process of getting a divorce. They do not live together but have joint custody. Examination revealed an alert but ill-looking child with all anthropometric measurements below the third percentile. He had several bruises at different stages of healing all over the body, including ecchymosis in the epigastric area. Initial CBC, coagulation profile, and CMP were normal. Skeletal survey showed mildly displaced supracondylar fracture of the right humerus and bulging out deformity of the medial cortex of the left distal radius, suspicious for a buckle fracture, and an oblique fracture through the midshaft of the left femur. The ophthalmologist reported retinal pinpoint hemorrhage in the left eye. CT of the brain showed chronic subdural effusion. Of the following, which is the most important step in his management?

A. Consult with a neurosurgeon.

B. Order an ultrasound of the abdomen.

C. Order a blood transfusion.

D. Transfer to the PICU and inform child protective services.

Preferred response: D

Rationale

This child has suffered severe inflicted injury with failure to thrive (FTT). He needs urgent CPS and PICU evaluations. The constellation of symptoms and signs of nonaccidental injury is present, and the ophthalmology report supports the diagnosis. CT of the abdomen is superior to ultrasound of the abdomen to diagnose abdominal injury. There is no obvious active bleeding that will warrant blood transfusion. The subdural effusion does not require urgent neurosurgical consult. The child has multiple bone fractures and an orthopedics consult will be done while

the child is in the PICU.

2. After he has been transferred to the PICU and CPS has been informed, what is the next step in the management of this child?
   A. CBC with differential
   B. Skeletal survey
   C. Ultrasound of the abdomen
   D. Coagulation profile
   Preferred response: B

Rationale

Skeletal survey may reveal rib fractures and other skeletal injuries. The child's injury was most likely inflicted by the mother's boyfriend who took care of the child when mother was out of the house. The bruises seen on the back are probably due to forceful handling and shaking. The location of the bruises in the posterior-medial aspect of the chest corresponds to location of the ribs. CBC with differential will also be helpful later to rule out bruises due to thrombocytopenia. Ultrasound of the abdomen will not rule out abdominal injury after the skeletal survey. CT of the abdomen is superior to ultrasound of the abdomen to diagnose abdominal injury. The coagulation and blood type profile will not be required immediately unless indicated in the course of the illness.

3. Which of the following bruises is most suspicious for inflicted injury to a child?
   A. Bilateral knee bruising in a 3-year-old child
   B. Bruising of the medial thigh in an 11-year-old girl
   C. Bruising over the vertebral processes on the posterior trunk of a 5-year-old boy
   D. Multiple bruises of different colors on a toddler's forehead
   Preferred response: B

Rationale

Inflicted bruises are often bilateral, widely distributed, and located on soft tissue areas of the body that are unlikely to make surface contact during a fall. They may take the shape of the inflicting object (eg, fingers, a hand print, linear whip marks from a belt, or loop marks from a folded belt or cord). They frequently are found on the posterior trunk, buttocks, and the posterior side of the extremities because the victim naturally would be trying to run away from the perpetrator. Bruise color is not a reliable indicator of the time an injury occurred. Bruises resolve and therefore change color at different rates depending on their location and the force with which they were inflicted. Nevertheless, documenting bruise color is important, particularly with the presence of bruises of markedly different colors at the same time, which suggest that the child may have been abused on more than one occasion. A simple gingerbread man drawing of the child's body, marked with the locations of all the child's injuries, is a concise descriptive tool that will quickly jar a physician's memory before any legal proceeding.

4. Which of the following statements is true regarding abusive head trauma (AHT)?

A. The morbidity associated with AHT is similar to the morbidity seen after accidental head trauma.

B. Direct impact is the major contributor to cerebral injury seen after AHT.

C. The C-spine must be immobilized and evaluated for injury in all cases of AHT.

D. Retinal hemorrhages must be present to confirm the suspicion of AHT.

Preferred response: C

Rationale

Most cases of head injury in children are accidental (90% in one study). However, the majority of deaths (80%) occur in children who are victims of child abuse. Outcome studies comparing children who survive accidental and nonaccidental head trauma show significantly higher morbidity rates in the nonaccidental victims.

The infant's upper cervical spinal cord is predisposed to injury because of the increased ligament elasticity; poorly supportive paraspinal muscles; incompletely ossified vertebrae with flattened, horizontal facet joints; and increased cord mobility within the cervical canal. In addition, an infant's large head causes traction injury to the upper cervical cord during acceleration and deceleration. This combination of factors requires that the infant with suspected AHT be immobilized in a cervical collar until the cervical spine can be thoroughly evaluated for injury.

Nonaccidental trauma (eg, shaking) generates rotational force as a consequence of rapid acceleration and deceleration movements of the head, resulting in distortion of both gross and microscopic cortical structure. The tearing of cerebral bridging veins creates a subdural hematoma. Axons that are torn at the microscopic level result in neuron death and global cerebral injury. Although subdural hematomas are a hallmark of shaken baby syndrome (SBS), they are rarely life-threatening lesions. The increased morbidity and mortality associated with AHT is attributed to brain injury at the cellular level. This cellular injury has been called diffuse axonal injury or traumatic axonal injury. Furthermore, increased vasoreactivity at the site of damaged axons causes a rapid onset of diffuse cerebral edema, which increases intracranial pressure (ICP) and compromises blood flow to vital areas of the brain.

Magnetic resonance imaging (MRI) is not readily available and requires sedation, but it is a better tool for identifying subarachnoid hemorrhage, petechial hemorrhage, infarction, hypoxic-ischemic encephalopathy, and axonal injury than is a CT scan. Subtle evidence of AHT and its consequent secondary brain injury is more easily seen on an MRI. In addition, an MRI is a more useful forensic tool than is a CT scan during a child abuse investigation. MRI ultimately should be used in all forensic child abuse investigations. Hemoglobin degradation within a central nervous system bleed occurs in a predictable sequence and can be roughly timed. Each hemoglobin degradation product has a unique appearance on T1- and T2-weighted images, and an experienced neuroradiologist may be able to narrow down the time of central nervous system injury; this is not possible with CT scans.

The diagnosis of SBS is made in the presence of a constellation of signs (ie, subdural hemorrhage, retinal hemorrhage, and skeletal injury). The mechanisms of injury proposed to cause subdural hematoma and retinal hemorrhage have been discussed. Posterior rib fractures occur when the infant's chest is compressed during shaking. Metaphyseal fractures are thought to occur as the legs and arms are flailed

back and forth. Only a small percentage of cases will have all three signs of SBS (ie, subdural hematomas, retinal hemorrhages, and skeletal injury). More than half of the cases will show both subdural hematoma and retinal hemorrhage, but the presence of subdural hemorrhage or retinal hemorrhage alone still suggests the diagnosis of SBS.

Chapter 123: Violence-Associated Injury to Children

---

1. A 16-year-old male was admitted to the ICU due to multiple wounds caused by a firearm when he was involved in a fight with a rival gang. After he was stabilized and you discussed his clinical condition with his parents, they voiced concerns about their son's recovery and mentioned other problems related to him. Their son was suspended when he was caught carrying a gun in school. While counseling the family about youth and school violence, what is the most appropriate statement?

   A. Effective violence intervention programs only have a primary objective.

   B. Female sex is the most important risk factor for school violence.

   C. Previous victimization is not associated with becoming a perpetrator of violent acts or abuse.

   D. Successful violence intervention programs stress self-awareness and control, problem-solving, and conflict resolution.

   Preferred response: D

Rationale

School-based preventive programs, family-based programs, and street outreach programs can lower the rates of violence and aggressive behaviors when implemented early in a child's life. These programs develop skills that include self-awareness and control, problem-solving, and conflict resolution.

Violence rates in the United States are declining, but rates for adolescent violence are increasing, and adolescents can be either perpetrators or victims. School violence includes various behaviors such as bullying, assault, fighting, and gang violence. Risk factors for perpetration are similar to those for victimization. Urban areas have higher rates of school violence. Adolescent perpetrators and victims of violence are at risk for committing future violent acts. Effective violence intervention programs have a multidisciplinary approach that includes family members, physicians, social services, and mental health professionals.

2. A 3-year-old boy was hurt physically by his father, and then he witnessed his father kill his mother. Your team on the ICU is caring for him. The boy has multiple lesions related to the incident, and he will recover soon. During rounds, you explain to the residents that the child will recover from the physical wounds but he will need counseling in the future. One of the residents asks if the child, due to his age, will forget the incident and recover without any short- or long-term problems. What is the most appropriate response to the resident's question?

A. The child will have short-term problems but will probably forget everything soon due to his age.

B. The child will confront both short- and long-term effects.

C. Victimization does not predispose the child to future acts of violence due to his age.

D. Witnessing violence is not a risk factor for long-term problems.

Preferred response: B

Rationale

An episode of violence-associated injury in a child is usually accompanied by visible and invisible factors that should be considered in the current and future treatment of the child. It is important for the practitioner to examine the factors that influence a child's physical and psychosocial well-being after experiencing a traumatic event, because these factors are often difficult to isolate, define, and quantify. In particular, factors related to psychosocial well-being are often overlooked due to their nonspecific presentation and the clinician's unfamiliarity.

Children exposed to violence-associated injury might experience short- or long-term psychosocial and emotional effects. Short-term effects can include child distress, emotional dysregulation, attention deficit hyperactivity disorder (ADHD), anger, depression, anxiety, posttraumatic stress disorder (PTSD), and conduct disorders. Long-term consequences include internalized and externalized psychological problems such as legitimization, adult depression, somatic problems, aggression, and PTSD, and behavioral problems such as substance abuse and health risk behaviors. All these problems are additionally linked to suicidality, obesity, hypertension, and cardiovascular diseases as well as failure in school, incarceration, poverty, and an unproductive and unhappy life as an adult.

Chapter 124: Principles of Drug Disposition in the Critically Ill Child

1. In considering the ontogeny of drug action, the age-related differences in effectiveness are determined mostly by:

A. Developmental changes in receptor numbers

B. Developmental changes in drug absorption

C. Developmental changes in pharmacokinetics and pharmacodynamics

D. The chemical class of the drug molecule

Preferred response: C

Rationale

Pharmacokinetic processes that influence drug disposition include absorption, distribution, metabolism, and excretion. Both ontogeny and critical illness may significantly impact any of these processes. Metabolism may be further affected by genetic differences in involved enzymes. Ontogeny and critical illness affect

pharmacodynamics in infants and children, although formal study of these effects is limited.

2. Which of the following is true regarding drug metabolism in the newborn?
   A. All CYP isomers mature at the same rate following birth.
   B. Phase I metabolism occurs at adult levels at birth.
   C. Phase II metabolism increases the hydrophobicity of drug molecules.
   D. The immaturity of drug metabolic pathways generally results in a prolongation of the drug half-life compared with that seen for the same drug in a 1-year-old.
   Preferred response: D

Rationale

The biotransformation of endogenous and exogenous substances occurs primarily in the liver, although the adrenal gland, placenta, kidney, gut, and skin are also capable of metabolizing compounds. Once a drug enters the hepatocyte, it may be transformed by one or more enzymatic reactions. These pathways, or phase I reactions, include oxidation, reduction, hydrolysis, and hydroxylation. In general, these reactions are responsible for transforming compounds into more polar, less lipid-soluble molecules that are more rapidly eliminated by the kidney, biliary system, or lung. Of the enzyme systems capable of metabolizing drugs, the hepatic cytochrome P-450 (CYP) mixed-function oxidase system has been studied in greatest detail. It is responsible for most of the phase I reactions catalyzed in the human liver.

During fetal life, these enzymes are present at 30% to 60% of adult activity in vitro. Following birth, total CYP levels increase, approaching adult range by age 1 year. Activity of all CYP enzymes is generally thought to be considerably lower in children, particularly neonates and infants, than in adults.

Conjugation reactions, or phase II reactions, synthesize more water-soluble compounds by combining a substance with an endogenous molecule to enhance excretion of that substance. Glucuronide, sulfate, and glycine are the common endogenous molecules to which drugs are bound. Glucuronidation is the most common conjugation pathway because of the availability of glucuronic acid and the variety of functional groups with which it can combine. The uridine 5′-diphosphate glucuronosyltransferases (UGTs) participate in the biotransformation of at least 100 drugs. The activity of a number of UGTs is decreased in the fetus and neonate, as assessed by in vitro studies. In addition, there is ample in vivo evidence of deficient glucuronidation in infants and particularly neonates.

3. A 14-year-old boy is admitted to the pediatric floor for fever and malaise after suffering a minor cut on his torso during a beach trip 1 week ago. Shortly after arrival, the nursing staff evaluates the child and activates the rapid response team. You find the child in shock, with the following vital signs: blood pressure, 43/24 mm Hg; heart rate, 154 beats/min; capillary refill, 6 seconds; temperature 34.4°C. Resuscitation efforts start immediately, and the child is transferred to the PICU. Despite fluids and pressors, the child's condition deteriorates and he is placed on extracorporeal membrane oxygenation (ECMO). Antibiotic therapy for presumed septic shock is started with vancomycin and gentamicin. The most likely effect on the pharmacokinetics of these drugs during ECMO is:

A. Decreased volume of distribution, decreased half-life, and decreased clearance

B. Decreased volume of distribution, decreased half-life, and increased clearance

C. Increased volume of distribution, increased half-life, and decreased clearance

D. Increased volume of distribution, increased half-life, and increased clearance

Preferred response: C

Rationale

A large number of studies have looked at the disposition of gentamicin and vancomycin during ECMO. Increased volume of distribution, increased half-life, and decreased clearance compared with control or post-ECMO values were demonstrated in the majority of these studies.

4. Which of the following drugs is managed with a target-effect strategy as opposed to target-concentration strategy?

A. Epinephrine

B. Gentamicin

C. Pentobarbital

D. Vancomycin

Preferred response: A

Rationale

The target-concentration strategy can be considered for drugs that are used long term to treat clinical problems that manifest themselves intermittently. Such problems include reversible reactive airway disease, seizures, and cardiac dysrhythmias. Application of this therapeutic strategy requires recognition that certain target serum concentrations are associated with either the therapeutic or toxic effects attributed to a given pharmacologic agent. It is important to remember that these target-concentration ranges are determined using population-based data rather than individual patient data. Therefore the so-called therapeutic or toxic ranges may not be strictly applicable to the patient currently being treated. However, they serve as useful guides for the initiation and ongoing monitoring of therapy. As part of this ongoing monitoring, effective use of the drug analysis laboratory is essential.

Pharmacology describes the interactions between drugs and/or drug metabolites and biosystems. These interactions can be described by several processes. A clear understanding of basic pharmacology principles will increase the likelihood that any treatment goal will be successfully accomplished with minimal adverse effects.

5. Which of the following is a pharmacodynamic process?

A. Absorption

B. Distribution

C. Excretion

D. Receptor activation

Preferred response: D

Rationale

In contrast to pharmacokinetics, which operationally describes what the body does to the drug, pharmacodynamics deals with what the drug does to the body. As such, this discipline within pharmacology deals with the mechanisms of action of drugs, their safety profile, drug-receptor interactions, and receptor-effector coupling phenomena.

Chapter 125: Molecular Mechanisms of Drug Actions: From Receptors to Effectors

---

1. Which of the following statements regarding receptors is true?
   A. Administration of a receptor antagonist abolishes the effect mediated by the receptor, whether or not the agonist is present.
   B. G protein–coupled receptors are complex signaling machines that participate in most physiologic and pathophysiologic processes and represent the target, directly or indirectly, of approximately 40% of all current therapeutic agents.
   C. Homologous desensitization refers to processes in which the activation of one type of receptor can result in the desensitization of other types of receptors.
   D. Receptors can be broadly divided into three categories: (1) G protein–coupled receptors (metabotropic); (2) channel-linked receptors (ionotropic); and (3) nuclear receptors.

   Preferred response: B

Rationale

Administration of a receptor antagonist in the absence of the agonist results in no effect because antagonists bind to receptors but do not activate them.

Receptors can be broadly divided into four (and not three) categories: (1) G protein–coupled receptors (metabotropic); (2) channel-linked receptors (ionotropic); (3) enzyme-linked receptors; and (4) nuclear receptors.

Homologous desensitization is a process in which only the activated receptor is "turned off" or desensitized, whereas heterologous (cross-) desensitization refers to processes in which the activation of one type of receptor can result in the desensitization of other types of receptors.

2. What is the mechanism of action behind the inotropic effect of β-adrenergic agonists?
   A. Activation of adenylate cyclase with increased cAMP, which activates protein kinase A (PKA) resulting in phosphorylation of voltage-gated L-type Ca^{2+} channels and ryanodine receptor with an increase in free intracellular calcium and subsequent contraction
   B. Activation of adenylate cyclase with increased cAMP, which activates PKA, resulting in phosphorylation of phospholamban and troponin I, which speed up Ca^{2+} reuptake by sarcoplasmic reticulum and dissociation of Ca^{2+} from the

myofilaments, respectively

C. Binding to troponin C and stabilizing its interaction with Ca^{2+} resulting in prolonged interaction of actin-myosin filaments and improved contraction

D. Inhibition of phosphodiesterase type III with increased cAMP, which activates PKA, resulting in phosphorylation of voltage-gated L-type Ca^{2+} channels and ryanodine receptor with an increase in free intracellular calcium and subsequent contraction

Preferred response: A

Rationale

Responses C and D pertain to the mechanism of action behind the inotropic effect of phosphodiesterase type III inhibitors (eg, milrinone) and Ca^{2+} sensitizers (eg, levosimendan), respectively. Response B describes the mechanism of action behind the lusitropic effect of β-adrenergic agonists and phosphodiesterase type III inhibitors.

3. Activation of which of the following receptors causes hyperpolarization of the cell membrane and decreased cellular excitability?

A. Acetylcholine receptors

B. Gamma-aminobutyric acid receptors

C. Glutamate receptors

D. Nicotinic receptors

Preferred response: B

Rationale

Activation of receptors of inhibitory mediators provokes hyperpolarization of the cell and therefore decreases cellular excitability; they are a group that includes γ-aminobutyric acid A ($GABA_A$) and glycine receptors. These ligand-gated ion channels are selective for anions such as chloride (Cl^-) or phosphorus (PO_4^{3-}). GABA is the major inhibitory neurotransmitter in the central nervous system, and drugs that potentiate GABAergic inhibition in the brain, such as benzodiazepines and barbiturates, result in sedation and hypnosis. Benzodiazepine agonists enhance Cl^- ion conductance induced by GABA by increasing the frequency of channel-opening events, while barbiturates seem to do so by increasing the duration of the GABA-gated channel openings. Both classes of agents bind to sites on the $GABA_A$ molecule that are different from each other and also from the GABA receptor site.

Receptors of excitatory mediators (glutamate, aspartate, and acetylcholine), which comprise the *N*-methyl-D-aspartate (NMDA) and the nicotinic acetylcholine receptors, are receptors whose activation provokes depolarization of the cell, leading to propagation of the action potential and, ultimately, secretion of a neuromediator and muscular contraction, for example. These receptors are permeable to monovalent and divalent cations, mainly Na^+, K^+, Ca^{2+}, and magnesium (Mg^{2+}).

4. Which of the following medications acts as a noncompetitive surmountable *N*-methyl-D-aspartate (NMDA) receptor antagonist?

A. Diazepam

B. Ketamine

C. Midazolam

D. Phenobarbital

Preferred response: B

Rationale

Ketamine, a dissociative anesthetic frequently used in the pediatric ICU, is a noncompetitive surmountable NMDA receptor antagonist that acts by preventing the opening of ion channels by glutamate. In addition, the potential neuroprotective effects of ketamine appear to be mediated via NMDA receptor blockade.

GABA is the major inhibitory neurotransmitter in the central nervous system, and drugs that potentiate GABAergic inhibition in the brain, such as benzodiazepines and barbiturates, result in sedation and hypnosis. Benzodiazepine agonists enhance Cl^- ion conductance induced by GABA by increasing the frequency of channel-opening events, while barbiturates seem to do so by increasing the duration of the GABA-gated channel openings. Both classes of agents bind to sites on the $GABA_A$ molecule that are different from each other and also from the GABA receptor site.

5. Which of the following medications causes increased inotropy by binding to troponin C and stabilizing its interaction with calcium?

A. Digoxin

B. Epinephrine

C. Levosimendan

D. Milrinone

Preferred response: C

Rationale

Ca^{2+} sensitizers (eg, levosimendan), a new class of inotropic agents, have been developed. They improve cardiac contractility by binding to troponin C and stabilizing its interaction with Ca^{2+}, which results in prolonged interaction of actin-myosin filaments. One possible limitation of some Ca^{2+} sensitizers is worsening diastolic function due to facilitation of cross-bridging at diastolic Ca^{2+}-concentrations. However, this phenomenon does not appear to be the case for levosimendan, because its binding to troponin C is dependent on $[Ca^{2+}]_i$ (ie, when $[Ca^{2+}]_i$ increases during systole, it facilitates actin-myosin interaction and when $[Ca^{2+}]_i$ decreases during diastole, it does not facilitate this interaction). One potential beneficial effect of these agents compared with catecholamines and phosphodiesterase (PDE) III inhibitors comes from the fact that they do not increase $[Ca^{2+}]_i$ and, as such, have neutral effects on myocardial oxygen demand and heart rhythm.

β-Adrenergic receptor stimulation by catecholamines activates a guanosine triphosphate–binding protein (Gs), which stimulates adenylate cyclase to produce cyclic adenylate monophosphate (cAMP) while PDE III inhibitors (eg, milrinone) prevent cAMP degradation. The resulting increase in cAMP activates protein kinase A, which in turn phosphorylates intracellular targets, including voltage-gated L-type

Ca^{2+} channels, RyR2, phospholamban, and troponin I. Phosphorylation of voltage-gated L-type Ca^{2+} channels enhances Ca^{2+} entry into the cytosol with subsequent increase in calcium-induced-calcium release from the sarcoplasmic reticulum (SR) and contraction (positive inotropic effect of catecholamines and PDE III inhibitors). In contrast, phosphorylation of phospholamban activates SR Ca^{2+}-adenosine triphosphatase with increased Ca^{2+} transport from the cytosol back to the SR and thus promotes relaxation (positive lusitropic effect of catecholamines and PDE III inhibitors). This action also contributes to the overall gain in cardiac excitation-contraction coupling by increasing the SR Ca^{2+} content available for the next contraction. However, such increased loading of the SR with Ca^{2+} may be a key factor in the development of Ca^{2+}-mediated arrhythmias.

Digoxin enhances myocardial contractility, although modestly, by inhibiting the Na^+/K^+ adenosine triphosphatase pump with a resultant mild increase in intracellular Na^+. This increase of Na^+ subsequently inhibits the extrusion of Ca^{2+} from the cytosol outside the cell by the sarcolemmal Na^+/ Ca^{2+} exchanger. Ca^{2+} not extruded from the cytosol is stored in SR and allows increased release of Ca^{2+} during the next contraction.

Chapter 126: Adverse Drug Reactions and Drug-Drug Interactions

---

1. Which of the following drugs can cause symptoms of methadone withdrawal when added to the regimen of patients who are being weaned from long-term opiate sedation?

   A. Fentanyl

   B. Gentamycin

   C. Ibuprofen

   D. Phenytoin

   Preferred response: D

Rationale

The addition of phenobarbital or phenytoin to a regimen of methadone, which may be used in the ICU for the purpose of weaning a patient from long-term opiate sedation, may present a potential for significant drug-drug interaction. The reduced plasma concentration of methadone could result in signs of methadone withdrawal.

2. Which of the following drugs can cause increased plasma levels of methadone?

   A. Carbamazepine

   B. Fluconazole

   C. Phenobarbital

   D. Phenytoin

   Preferred response: B

Rationale

Analgesic pharmacokinetic drug-drug interactions can mediate clinically relevant effects. CYP3A is involved in the metabolism of methadone. Methadone metabolism is induced by rifampin and results in enhanced clearance of methadone. In addition, phenobarbital, phenytoin, carbamazepine, nevirapine, and efavirenz have the potential to decrease methadone blood concentrations. Inhibition of CYP3A can result in increased plasma levels of methadone. For example, fluconazole inhibits metabolism of methadone. Other inhibitors of CYP3A include itraconazole, metronidazole, ketoconazole, voriconazole, clarithromycin, and erythromycin.

3. Which of the following drugs can cause an increase in digoxin levels?

   A. Amiodarone

   B. Caffeine

   C. Epinephrine

   D. Indomethacin

   Preferred response: A

Rationale

As a substrate for P-glycoprotein (PGP), digoxin exhibits reduced renal and nonrenal clearance when a PGP inhibitor is added to the drug regimen. The plasma levels of digoxin may double or quadruple, demanding close monitoring for digoxin toxicity. PGP inhibitors include amiodarone, clarithromycin, cyclosporine, diltiazem, erythromycin, ketoconazole, itraconazole, propafenone, quinidine, midazolam, and verapamil.

4. Which of the following drugs augments nitric oxide's pulmonary vasodilator effects via cyclic guanosine monophosphate (cGMP) by selective inhibition of type 5 phosphodiesterase, the enzyme responsible for the degradation of cGMP?

   A. Adenosine

   B. Dopamine

   C. Epoprostenol

   D. Sildenafil

   Preferred response: D

Rationale

The combination of sodium nitroprusside and sildenafil may produce additive hypotensive effects. Studies have shown sildenafil to be effective in the treatment of pulmonary hypertension and chronic lung disease in pediatric and neonatal critical care patients. The increased use of this medication, especially in cardiac patients, has necessitated heightened surveillance of potential interactions. Contact between sodium nitroprusside molecules and erythrocytes or the vascular wall results in the generation of nitric oxide. Nitric oxide subsequently stimulates the cGMP second messenger system in vascular smooth muscle upon activation of soluble guanylyl cyclase. The molecular process of increasing intracellular concentrations of cGMP translates to vasodilation and the resultant physiologic effect of reduced blood

pressure. Sildenafil augments the response to cGMP through selective inhibition of type 5 phosphodiesterase, the enzyme that catalyzes degradation of cGMP. Therefore sildenafil can react similarly with other drugs (eg, nitroglycerin and hydralazine) that promote the generation of a nitric oxide species.

Chapter 127: Principles of Toxin Screening, Assessment, and Detoxification

---

1. A severe ethylene glycol intoxication is suspected in an unknown toxic alcohol ingestion when there is:
   A. An elevated serum osmolality measured by freezing point depression
   B. A normal serum osmolality measured by vapor pressure method
   C. A depressed anion gap
   D. A normal anion gap
   Preferred response: A

Rationale

Ethylene glycol will contribute unmeasured, osmotically active molecules to the blood, which will elevate the serum osmolality above that value calculated with the conventional, osmotically active blood components (ie, BUN, glucose, sodium). Thus the measured serum osmolality, when performed by the "freezing point" methodology, will reveal a gap. However, the "vapor pressure" method allows some ethylene glycol metabolites to escape detection and will be falsely normal in a case of ethylene glycol poisoning. Ethylene glycol is metabolized first in the liver by the enzyme alcohol dehydrogenase to glycoaldehyde. This is then further transformed by degradation to glyoxylate, glycolate, and oxalate molecules, present as unmeasured anions and acids (eg, glycolic and oxalic acids) in the blood. Further metabolism of ethylene glycol metabolic products into glycine exhausts bicarbonate reserves and adds to the acid production. Lactic acid is also generated in large amounts during ethylene glycol poisoning, resulting in profound acidemia. These metabolic pathways account for both an elevated anion gap, as well as a dramatic metabolic acidosis.

2. Methemoglobinemia is clinically characterized by which of the following?
   A. Bright "cherry red" venous blood
   B. Exposure to an oxidizing chemical
   C. No change with the infusion of methylene blue
   D. Reliable oxygen saturation readings by pulse oximetry
   Preferred response: B

Rationale

The first step in the creation of methemoglobin requires the presence of an oxidizing drug, food, or chemical. Methemoglobin represents the formation of oxidized iron (ferric) within hemoglobin, such that the hemoglobin becomes nonfunctional in terms of oxygen carriage and unloading in the tissues. Since the methemoglobin molecule absorbs more light at 660 and 940 nm than does either reduced hemoglobin or oxyhemoglobin, it imparts a dark brown color to the blood and conveys a grayish, cyanotic tone to the skin. For the same reason, pulse oximetry is rendered inaccurate because it depends on the detection of light absorption of oxyhemoglobin and cannot correct for the presence of another light-absorbing but nonfunctional hemoglobin, giving variably falsely high or falsely low values. With the IV infusion of the correct dose of the antidote, methylene blue, the intensivist can expect a resolution of the child's respiratory complaints and the return to a normal skin color, often within minutes.

3. Life-threatening iron poisoning is characterized by:
   - A. Depressed anion gap
   - B. Elevated osmolar gap
   - C. Negative toxic screen
   - D. Metabolic alkalosis

   Preferred response: C

Rationale

Severe, life-threatening iron poisoning rapidly takes the patient to a stage characterized clinically by the presence of both hypovolemic shock and a metabolic acidosis. The elaboration of excess, unmeasured acids in the blood elevates the anion gap. However, these molecules are not osmotically active and so should not ordinarily affect the measured serum osmolarity. Because the conventional "toxic screen" as performed in most hospitals does not include iron, it will be reported as negative. The intensivist must order specifically a serum iron concentration.

4. Anticholinergic syndrome differs from sympathomimetic syndrome by the presence of which of the following?
   - A. Dilated pupils
   - B. Dry skin
   - C. Fever
   - D. Tachypnea

   Preferred response: B

Rationale

Anticholinergic syndrome may have features that are similar to those of the sympathomimetic toxidrome. Examination of the skin usually provides clues to differentiate between the two because the patients will have dry skin in this scenario versus increased diaphoresis with sympathomimetic toxicity. Hypertension and tachycardia are typically less severe than that seen with sympathomimetics. Also, the dilated pupils of the anticholinergic syndrome are nonreactive because of associated cycloplegia.

5. The herbs senecio, heliotrope, and comfrey are capable of producing which disease pathology?
   A. Asthma, urticaria, angioedema
   B. Coma, seizures, death
   C. Diarrhea, anxiety, hypertension
   D. Hepatic veno-occlusive disease
   Preferred response: D

Rationale

Hepatic veno-occlusive disease may be caused by the ingestion of senecio, heliotrope, and comfrey. Echinacea is known to cause asthma, atopy, urticaria, and angioedema.

Diarrhea, anxiety, hypertension, and insomnia are characteristic of ginseng use. Use of laetrile leads to cyanide toxicity, with manifestations of coma, seizures, and death. Nutmeg use causes hallucinations, emesis, and headaches.

6. An adolescent exhibiting the agitated delirium produced by jimsonweed ingestion will have a clear sensorium after the administration of which of the following?
   A. Diphenhydramine
   B. Flumazenil
   C. Naloxone
   D. Physostigmine
   Preferred response: D

Rationale

Substances of abuse may cause delirium or hallucinations in the adolescent. Jimsonweed *(Datura stramonium)* plant seeds, which contain atropine and other anticholinergic chemicals, can be intentionally chewed by adolescents for their euphoric (and delirium-producing) effects caused by a central anticholinergic syndrome. Physostigmine can be of benefit in pediatric patients who have ingested jimsonweed seeds *(D. stramonium)* or other pure anticholinergic agents; however, caution is dictated in unknown poisonings in which cardiac conduction toxicity is a consideration because physostigmine itself can cause severe cardiac toxicity, bradycardia, and asystole.

Chapter 128: Toxidromes and Their Treatment

---

1. The constellation of miosis, coma, and respiratory depression is most consistent with exposure to which agent?
   A. Atropine
   B. Clonidine

C. Diphenhydramine

D. Lorazepam

Preferred response: B

Rationale

Miosis, coma, and respiratory depression are hallmarks of opioid exposure, but other drugs such as central presynaptic α_2-agonists can also cause those symptoms. An example of this type of drug is clonidine.

2. Physostigmine is most appropriately indicated as an antidote for what agent?

A. Amitriptyline

B. Benzocaine

C. Methamphetamine

D. Scopolamine

Preferred response: D

Rationale

Physostigmine is an antidote for antimuscarinic toxicity. Scopolamine is such a drug. Although amitriptyline has antimuscarinic properties, the use of physostigmine in tricyclic antidepressant overdose is contraindicated.

3. Which of the following signs is most suggestive of anticholinergic toxicity as opposed to the sympathomimetic toxidrome?

A. Dilated, nonreactive pupils

B. Hypertension

C. Hyperthermia

D. Tachycardia

Preferred response: A

Rationale

The anticholinergic toxidrome, more appropriately referred to as an *antimuscarinic toxidrome,* is produced by a number of agents that possess antimuscarinic properties as their primary effect or as a "side effect." Muscarinic receptors are located in the central nervous system, the target organs of the parasympathetic nervous system, and the sweat glands (sympathetic nervous system).

The syndrome may have features that are similar to those of the sympathomimetic toxidrome. Examination of the skin usually provides clues to differentiate between the two because the patients will have dry skin in this scenario versus increased diaphoresis with sympathomimetic toxicity. Hypertension and tachycardia are typically less severe than that seen with sympathomimetics. Also, the dilated pupils of the anticholinergic syndrome are nonreactive because of associated cycloplegia.

4. Which of the following drug overdoses is most likely to respond to atropine?

A. Clonidine

B. Digoxin

C. Diltiazem

D. Propranolol

Preferred response: B

Rationale

An overdose of digoxin presents with nausea, vomiting, lethargy or confusion, and cardiac dysrhythmias. Although virtually every rhythm has been described in persons with digoxin toxicity, bidirectional ventricular tachycardia and atrial tachycardia with atrioventricular block are characteristic. Sinus bradycardia or heart block may respond to atropine alone. More serious arrhythmias are an indication for treatment with digoxin-specific Fab fragments (eg, Digibind and DigiFab).

An acute overdose of β-adrenergic antagonists results in bradycardia, hypotension, and conduction delay. Toxicity is generally much lower than with calcium channel antagonists such as verapamil and diltiazem. Propranolol, by virtue of its sodium channel–blocking activity, causes QRS widening, exaggerated negative inotropy, chronotropy, and conduction delay. Treatment beyond monitoring is not necessary if the only manifestation is asymptomatic bradycardia. Patients with bradycardia and hypotension may respond to atropine, although it is expected that such patients would have decreased vagal tone to start with. β-agonists have variable effects in the presence of β-adrenergic blockade. Glucagon acts via a nonadrenergic receptor to increase intracellular cyclic adenosine monophosphate and improve cardiac contractility. Patients who do not respond to these measures, such as patients with calcium channel blocker overdose, should be considered for extracorporeal life support.

Verapamil possesses vasodilatory effects and potent cardiac calcium channel–blocking activity and may cause bradycardia, heart block, and myocardial depression. Diltiazem has effects similar to those of verapamil but is a less potent inhibitor of cardiac calcium channels. Treatment depends on the agent involved and the severity of toxicity. Except in extremely large ingestions, dihydropyridines produce hypotension and reflex tachycardia. These patients may respond to volume expansion alone. IV administration of calcium and vasopressors is indicated if the hypotension remains refractory to IV fluids. Verapamil and diltiazem overdose is further complicated by pump failure. These patients may benefit from inotropes such as dobutamine. Glucagon, which acts at a receptor other than the β receptor, increases cyclic adenosine monophosphate and has been reported to reverse refractory hypotension in persons with calcium channel overdose.

Reversal of opioid toxicity has been associated with pulmonary edema, although this has also been described in the setting of opiate toxicity itself. Anecdotally, naloxone has been reported to reverse clonidine overdose, although failure of naloxone to reverse clonidine has also been described. Occasionally naloxone administration has been associated with significant hypertension, which is usually short-lived and does not require treatment. If hypertension persists, treatment should consist of a short-acting antihypertensive agent such as nitroprusside so that the drug and its effects can be stopped quickly. This treatment will prevent the development of hypotension as the hypertensive crisis resolves.

5. In which of the following toxin-induced hyperthermia states has dantrolene

proven to be lifesaving?

A. Malignant hyperthermia

B. Neuroleptic malignant syndrome

C. Serotonin syndrome

D. Sympathomimetic toxicity

Preferred response: A

Rationale

Malignant hyperthermia is a genetically determined condition that is triggered by exposure to depolarizing neuromuscular blocking agents (succinylcholine) or inhalational anesthetic agents. It is a life-threatening condition that results from dysfunction of the ryanodine receptors, which elevates the intracellular calcium in somatic muscle cells, resulting in rigidity and muscle damage. This syndrome requires prompt intervention with aggressive cooling and treatment with dantrolene, which allows muscle relaxation through the blockade of calcium release from the sarcoplasmic reticulum.

6. Which of the following toxins causes metabolic acidosis through the generation of a substance other than lactate?

A. Carbon monoxide

B. Cyanide

C. Ethylene glycol

D. *Gyromitra* mushroom species

Preferred response: C

Rationale

Ethylene glycol is converted to a number of intermediate toxic products and ultimately to oxalate. This conversion results in severe metabolic acidosis, renal failure, and hypocalcemia through binding of oxalate to calcium to form crystals.

Cyanide binds to heme iron in the cytochrome complex IV of the electron transport chain, cytochrome C oxidase, resulting in inhibition of oxidative phosphorylation. Consequently, the patient is unable to use oxygen to produce adenosine triphosphate, and the result is energy failure. Signs and symptoms are nonspecific and reflect tissue hypoxia; however, a symptomatic patient with a lactate of 10 mmol/L or more is highly suspect for cyanide toxicity.

Carbon monoxide causes tissue hypoxia through several mechanisms: It binds with high affinity to oxygen-binding sites of hemoglobin; it binds to myoglobin and disrupts the transfer of oxygen from erythrocytes to mitochondria; it binds to mitochondrial cytochrome oxidase; and it interferes with electron transport and adenosine triphosphate production.

Ingestion of mushrooms from the group of hydrazine-containing mushrooms, including the *Gyromitra* species, will produce toxicity identical to INH through its interference with pyridoxal-5-phosphate and depletion of γ-aminobutyric acid.

7. Reversal of which of the following toxins is most likely to produce life-threatening withdrawal?

A. Dapsone
B. Diazepam
C. Digoxin
D. Morphine
Preferred response: B

Rationale

When given for a benzodiazepine overdose, flumazenil may precipitate acute withdrawal in the patient who habitually uses benzodiazepines or may unmask seizures caused by a coingested substance.

Chapter 129: Airway Management

1. You are being deluged with new admissions to the PICU, many of whom appear likely to require early endotracheal intubation. Which of the following patients currently meets criteria for intubation?
   A. A 30-kg 9-year-old girl with Guillain-Barré syndrome and progressive weakness is transferred from the routine unit. On supplemental oxygen (2 L O_2 by nasal cannula) an arterial blood gas reveals the following: pH, 7.36; PaO_2, 85 mm Hg; $PaCO_2$, 42 mm Hg; base deficit, 2. Her vital capacity is 250 mL; she can generate a negative inspiratory pressure of approximately −15 cmH_2O.
   B. A 20-kg 5-year-old boy who fell out of a tree is admitted after a CT scan of his head revealed a small left frontal subdural hematoma. SpO_2 is 99% on supplemental oxygen (2 L O_2 by nasal cannula). He is lethargic but opens his eyes when requested, speaks occasional but apparently random words, and withdraws to pain.
   C. A 45-kg 14-year-old girl has cystic fibrosis and probable pneumonia. Vital signs include a respiratory rate of 25 breaths per minute; heart rate, 110 beats per minutes; blood pressure, 115/60 mm Hg; temperature, 38.8°C. An arterial blood gas drawn while she was breathing supplemental oxygen with fraction of inspired O_2 of 0.40 reveals pH, 7.38; PaO_2, 92 mm Hg; $PaCO_2$, 50 mm Hg; and base excess, 5.
   D. A 12-kg 18-month-old child with croup has a respiratory rate of 20 breaths per minute with moderate intercostal retractions. He responded to nebulized racemic epinephrine twice in the ED but has again developed significant inspiratory stridor. SpO_2 is 92% on 2 L of oxygen via nasal cannula.
   Preferred response: A

Rationale

The girl with Guillain-Barré syndrome is currently maintaining adequate gas exchange on a modest level of supplemental oxygen. However, her vital capacity (VC) is only 8.3 mL/kg and her most negative inspiratory pressure (NIP) is only −15

cm H_2O. These two measurements demonstrate minimal respiratory reserve and place her at immediate risk of severe deterioration, should she develop atelectasis or accumulate mucus or anything else obstructing an airway. Commonly accepted thresholds for intubation on the basis of neuromuscular weakness include a VC <12-15 mL/kg and/or NIP less negative than −20 cm H_2O. The boy with head trauma has a Glasgow Coma Scale score of 10, which is above the usual threshold for intubation of 8. Although the girl with cystic fibrosis is hypercarbic, she is well compensated, indicating that her CO_2 retention is chronic and does not constitute immediate evidence of acute respiratory insufficiency. The infant with croup is adequately oxygenated with minimal supplemental oxygen, has only moderately increased work of breathing, and so far is responsive to racemic epinephrine. Options before intubation include continued treatment with epinephrine, a helium-oxygen mixture, and possibly steroids.

2. Which of the following classic descriptions of the young child's airway has been shown by recent imaging to be inaccurate?
   A. Absolute resistance to airflow is higher in newborns than in older children and adults.
   B. The epiglottis is found higher in the neck than in adults.
   C. The epiglottis is soft and omega-shaped rather than flat and rigid as in adults.
   D. The narrowest portion of the young child's airway, aside from the nasal valve, is at the cricoid cartilage.

   Preferred response: D

Rationale

Contrary to classic teaching, modern MRI and CT imaging have demonstrated that the young child's airway is narrowest at the level of the vocal cords, as is the case for older children and adults, not at the level of the cricoid cartilage. Resistance to airflow is higher in newborns as a result of the narrow nasal valve, small oral cavity, and narrow tracheal dimensions. The epiglottis is at the level of the first cervical vertebra at birth, descends to the level of the third vertebra by about 6 months, and is found at the level of the fifth or sixth vertebra by adolescence. The epiglottis is soft and omega-shaped. Its position near the base of the tongue and its vulnerability to edema result in greater potential to occlude the airway than in the older child or adult.

3. A 7-year-old boy was struck by a car while riding his bicycle near your hospital. He was unconscious at the scene but breathing spontaneously and was brought to your emergency department. On examination, he is noted to have a heart rate of 140 beats per minute, respiratory rate of 20 per minute, blood pressure of 85/60 mm Hg, and arterial oxygen saturation (SaO_2) of 92% on room air. He has a large laceration and hematoma in the right parietal area, bruising behind his right ear, crepitance over his right clavicle, and obvious fractures of both femurs with severe swelling of his thighs. He groans occasionally but does not open his eyes. In response to noxious stimuli, he flexes both arms. No movement is noted in his lower extremities. His pupils are equal and react to light. He has wandering conjugate eye movements. A gag reflex is present. Which of the following is the

most appropriate approach to managing this patient's airway?

A. Allow him to continue spontaneous breathing but provide supplemental oxygen to increase his saturations to 100% to ensure maximal brain tissue oxygenation.

B. Perform rapid sequence orotracheal intubation with atropine, thiopental, and succinylcholine.

C. Provide manual ventilation with 100% oxygen, followed by administration of fentanyl, midazolam, and rocuronium and orotracheal intubation.

D. Provide manual ventilation with 100% oxygenation, followed by administration of etomidate and rocuronium and nasotracheal intubation.

Preferred response: C

Rationale

The patient described has evidence of severe traumatic brain injury, a basilar skull fracture, and multiple other skeletal injuries, including bilateral femur fractures. In addition, his vital signs suggest that he is in shock, most likely from blood loss into fracture sites, although other possibilities have not yet been excluded. His Glasgow Coma Scale (GCS) score is 6. Of the options provided, C is the most appropriate approach to managing his airway. He should be manually ventilated with 100% oxygen to ensure that he is well oxygenated and ventilated so that neither hypoxemia nor hypercarbia leads to increased cerebral blood flow (CBF) and intracranial pressure (ICP). (In a patient with impending herniation, mild hyperventilation may be appropriate until diuretic therapy can be instituted.) Fentanyl and midazolam are unlikely to be associated with myocardial depression or vasodilatation and exacerbation of his hemodynamic instability. Rocuronium has an adequately rapid onset of action and is also largely free of deleterious cardiovascular adverse effects. Orotracheal intubation is usually accomplished more easily and rapidly than is nasotracheal intubation and minimizes the period when noxious stimuli promote intracranial hypertension. In addition, the patient has evidence of a basilar skull fracture (Battle sign), which is a contraindication to nasotracheal intubation.

Although he is marginally adequately oxygenated and breathing spontaneously and the presence of a gag reflex suggests that he may be able to protect his airway, current guidelines recommend intubation for patients with a GCS of 8 or less to control $Paco_2$ and prevent increased intracranial blood flow and subsequent elevation of ICP. Supplemental oxygen is certainly indicated to maximize brain tissue Po_2 but is not sufficient in a patient with evidence of such significant brain injury.

Rapid sequence orotracheal intubation with atropine, thiopental, and succinylcholine might be considered in a patient with isolated head trauma. Thiopental has a profound effect on cerebral metabolic rate for oxygen and can be an effective means of decreasing CBF and ICP. However, it is also a myocardial depressant and venodilator and is not recommended in patients with significant blood loss and hemodynamic instability. Succinylcholine continues to be widely used for emergency intubations but provides little advantage over other agents that have fewer adverse effects. It has been associated with massive hyperkalemia after

spinal cord injury, generally several days to months after trauma, and risking its use seems unwise. Finally, rapid sequence intubation includes not providing manual ventilation until the endotracheal tube is in place. In a patient with elevated ICP, the risk of progressive hypoxia and hypercarbia that would occur without manual ventilation is probably inappropriate.

Manual ventilation with 100% oxygen and intubation facilitated by etomidate and rocuronium would be a reasonable approach to managing this child's airway. However, nasotracheal intubation in a child with a probable basilar skull fracture, suggested in this patient by the presence of bruising behind the ear (Battle sign), is contraindicated. Some intensivists consider the adrenal insufficiency associated with etomidate sufficient reason to avoid use of the drug, although the concern is greatest in the setting of sepsis.

4. On a busy night in the PICU, several patients are experiencing worsening problems and newly admitted ones require evaluation. Which of the following patients is most likely to have adequate respiratory function without intubation in the near future?

   A. A 13-kg, 18-month-old boy with croup, severe stridor, and intercostal, supraclavicular, and abdominal muscle use who has increasing agitation following treatment with dexamethasone and nebulized racemic epinephrine; temperature (T) = 38.6°C, heart rate (HR) = 155, respiratory rate (RR) = 40, blood pressure (BP) = 120/60 mm Hg, and SaO_2 is 94% on fraction of inspired oxygen (FiO_2) of 0.40

   B. A 20-kg, 4-year-old girl with a recent viral gastroenteritis who now has tachypnea, diffuse crackles bilaterally, a gallop rhythm, and liver edge palpable 4 cm below the right costal margin; she has cardiomegaly and pulmonary edema on chest radiograph; echocardiogram reveals poor bilateral ventricular contractility; milrinone is infusing, but her BP is decreasing and she is having short runs of ventricular tachycardia; T = 38.1°C, HR = 140 beats per minute, RR = 45 breaths per minute, BP = 85/38 mm Hg, and SaO_2 is 91% on 30% oxygen

   C. A 40-kg, 12-year-old girl with Guillain-Barré syndrome with weakness of all extremities; her cranial nerves remain intact and she has both cough and gag reflexes; T = 37.6°C, HR = 95 beats per minute, RR = 30 breaths per minute, BP = 120/85 mm Hg, SaO_2 is 96%, arterial blood gas analysis while she is breathing 3 L oxygen by nasal cannula reveals pH 7.37, PaO_2 98 mm Hg, $PaCO_2$ 43 mm Hg; her negative inspiratory pressure is –15 cm H_2O; her vital capacity is 250 mL

   D. A 45-kg, 14-year-old boy with paraplegia resulting from an accident causing a T10 spinal cord injury 1 year ago who has a right lower lobe pneumonia and pleural effusion; he is awake and alert and is coughing up purulent secretions; T = 38.9°C, HR = 95, RR = 30, BP = 120/85 mm Hg, SaO_2 is 90%; arterial blood gas analysis while he is breathing 35% oxygen by simple mask reveals pH 7.37, PaO_2 62 mm Hg, $PaCO_2$ 43 mm Hg; his negative inspiratory pressure is –45 cm H_2O, and his vital capacity is 850 mL

   Preferred response: D

Rationale

Indications for intubation include abnormalities of blood gas exchange, airway obstruction, failure of the respiratory bellows apparatus, abnormalities of central nervous system respiratory drive, absence of airway protective reflexes, and severe hemodynamic instability. Although the boy with paraplegia, pneumonia, and pleural effusion is certainly at risk for deterioration and the need for mechanical ventilation, he does not appear to require immediate intubation. He is marginally adequately oxygenated, but his supplemental oxygen can be increased even with continued use of a simple face mask. Drainage of his effusion may further improve oxygenation. Although patients with high spinal cord injury are at risk for respiratory failure, most patients with injury below the level of T6 maintain adequate ventilation and lung inflation, using the diaphragm and upper intercostal muscles. This patient appears to have adequate muscle strength as evidenced by a cough effectively mobilizing sputum, as well as adequate vital capacity (>12-15 mL/kg) and inspiratory pressure more negative than –40 cm H_2O. His respiratory rate does not suggest that he is in imminent risk of tiring.

The boy with croup has severe upper airway obstruction with markedly increased work of breathing as evidenced by his agitation and use of accessory muscles. He has not responded to the available medical interventions of steroids and nebulized epinephrine. Although oxygenation remains adequate, he is at high risk for complete airway occlusion or overwhelming fatigue. Intubation before respiratory arrest occurs is indicated.

The boy with probable viral myocarditis has evidence of heart failure and impending cardiogenic shock, as well as potentially life-threatening arrhythmias. Although medical management may be modified to find more effective interventions, intubation at this time is indicated to decrease respiratory muscle work and allow distribution of cardiac output to other tissues, as well as to decrease the risk of cardiac arrest and an uncontrolled situation should one occur. Positive pressure ventilation may improve cardiac output and help manage her pulmonary edema, but intubation also may stimulate further arrhythmias or decrease venous return.

The 12-year-old girl with Guillain-Barré syndrome is maintaining adequate gas exchange and has airway protective reflexes. However, her vital capacity and negative inspiratory pressure provide evidence that she has little respiratory reserve. Her vital capacity of 250 mL is barely greater than a normal tidal volume (6 mL/kg), so she is unable to take a large breath to re-expand atelectatic areas of her lungs. Any further decrease in motor function will compromise her tidal volume, and adequate minute ventilation will require increased respiratory rate. Moreover, she does not have the strength to expel a mucous plug or clear her airway of oral secretions or a food particle, even if she can perceive its presence. Intubation is indicated to maintain adequate tidal volume and good lung expansion and provide airway protection.

Chapter 130: Anesthesia Effects and Organ System Considerations

---

1. Which of the following is associated with propofol infusion syndrome?

A. Hypokalemia

B. Metabolic alkalosis

C. Rhabdomyolysis

D. Tachycardia

Preferred response: C

Rationale

Propofol infusion syndrome (PRIS) is characterized by severe intractable bradycardia that leads to cardiac failure, severe metabolic acidosis, hyperlipidemia, rhabdomyolysis with consequent hyperkalemia, and renal failure. Prolonged propofol infusions (more than 48 hours) and infusion rates greater than 4 mg/kg/hr have been linked to PRIS. Priming factors such as critical illness (respiratory failure and traumatic brain injury) and triggering factors such as catecholamine and steroid infusion are associated with the syndrome. The underlying mechanism appears to be an inhibition of mitochondrial electron transport and impairment in oxygen utilization. As a result, there is a decreased ATP production and a decreased mitochondrial lipid metabolism, with an accumulation of toxic long fatty acid chains that are arrhythmogenic. Pediatric patients appear more susceptible than adults secondary to low glycogen stores and high need for fat metabolism.

2. Which of the following statements regarding local anesthetic agents is correct?

A. Amino amide local anesthetics are metabolized by plasma and tissue esterases.

B. Compared with adults, the unbound fraction of local anesthetics is lower in children.

C. Compared with adults, infants are at a lower risk for local anesthetic toxicity.

D. Compared with adults, the duration of action of local anesthetic agents is shorter in infants.

Preferred response: D

Rationale

Local anesthetic agents are classified as amino esters (cocaine, tetracaine, chloroprocaine, and prilocaine) or amino amides. The amino amides include bupivacaine, ropivacaine, levobupivacaine, and lidocaine and are potent sodium channel blockers. At toxic blood concentrations they can cause seizures, cardiac arrhythmias, and cardiac arrest that can be resistant to resuscitation.

Children are more at risk from local anesthetic toxicity because of their lower serum concentrations of α_1-acid glycoprotein (AAG) and albumin, which are the binding proteins for local anesthetics (LA). Therefore the unbound fraction of LA, which is the active drug, is increased, making infants and children more susceptible to local anesthetic toxicity (LAST). Another factor that can influence LAST in neonates and children is the slower metabolism and elimination of the local anesthetic agents.

The potency and duration of local anesthetic agents depend on lipophilicity, degree of ionization, protein binding, and the vasoconstricting properties of the drug. In general, the duration of action of local anesthetic agents is shortest in

neonates and infants. Metabolism of amides is by the liver's P-45O enzyme system, while metabolism of the ester compounds is by plasma esterases (butyrylcholinesterase) and tissue esterases.

3. When compared with pediatric liver transplant patients who do not have an increased risk for perioperative bleeding, pediatric liver transplant patients who receive recombinant activated factor VII (rFVIIa) have been shown to have which of the following?

   A. An increase in operating time

   B. An increased number of thromboembolic events

   C. No difference in blood loss

   D. The same number of thromboembolic events

   Preferred response: C

Rationale

Recombinant activated factor VII (rFVIIa, NovoSeven) is an analogue of the naturally occurring activated FVII and is a powerful hemostatic agent. It is approved by the US Food and Drug Administration for use in persons with congenital or acquired hemophilia with inhibitors who are actively bleeding or for prophylaxis before invasive surgery or procedures. rFVIIa directly enhances thrombin generation locally at the site of endothelial damage, where tissue factor is exposed, and indirectly enhances it on the activated platelet surface, creating the thrombin burst that generates enormous amounts of fibrin mesh in proximity to the damaged vasculature. Since it began to be marketed in 1999 in the United States, the number of publications regarding the off-label use for life-threatening hemorrhages of various origins in nonhemophiliac patients has exponentially increased, giving rFVIIa a potential role as a universal hemostatic agent.

Pediatric liver transplants have a higher incidence of vascular graft thrombosis because of the smaller caliber of the vascular grafts, and it is feared that the administration of rFVIIa can increase the incidence of vascular graft thrombosis. Kalicinski et al. reviewed 89 consecutive patients from 1 to 20 years of age who underwent cadaveric liver transplant. Twenty-eight of these patients had a high risk of intraoperative blood loss and received rFVIIa before undergoing the transplant procedure. When they were compared with 61 patients who had no increased intraoperative risk of blood loss, no difference was noted in blood loss, operating time, reexploration, and hospital stay. Interestingly, no thromboembolic events were observed in the group that received rFVIIa, whereas in the 61 patients who did not receive rFVIIa, 3 had hepatic artery thrombosis, 2 had portal vein thrombosis, and 1 had hepatic vein thrombosis. The authors suggest that despite the use of rFVIIa, the overall hemostatic balance remains modestly hypocoagulable.

4. Thromboelastrographic (TEG) tracings of hypocoagulable states during liver transplants show which of the following?

   A. Decreased r-time, increased k-time, increased maximum amplitude

   B. Increased r-time, increased α-angle, decreased maximum amplitude

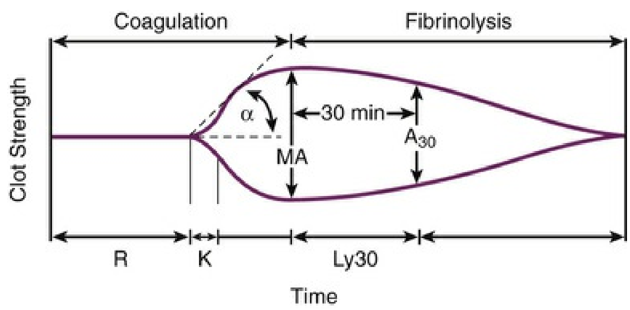
   C. Increased r-time, decreased α-angle, decreased maximum amplitude

   D. Decreased r-time, decreased α-angle, decreased maximum amplitude

Preferred response: C

Rationale

TEG has been in use for more than 60 years. Developed during World War II, it has had a revival with the advent of transplantation and the ability to perform more complex surgeries. Moreover, new technology has made this point of care test easier to execute, more reliable, and reproducible. TEG is a global dynamic assessment of hemostasis that can yield information on several different components of coagulation within 60 minutes. Its use for the guidance of blood component therapy in persons undergoing a liver transplant has been demonstrated. TEG measures the static viscoelastic properties of whole blood. As a clot begins to form in the sampling cup, the viscoelastic properties of the sample increase and an increase in amplitude is registered on the tracing. At the end of the test, a characteristic trace with two arms is created. Various measurements are derived from the tracing (see figure below). The r-time is the time in minutes from the start of the sample run until the first traces of clot mesh are detected (defined as an increase in amplitude of 2 mm). The r-time generally reflects factor levels. The k-time is the time elapsed between an amplitude of 2 and 20 mm on the TEG tracing and reflects the velocity of clot formation. The α-angle is the slope drawn from r to k. The angle reflects fibrinogen activity. The maximum amplitude is the greatest vertical amplitude. It reflects clot strength and indirectly assesses platelet number and function and fibrin formation. The clot lysis index (A60) is the amplitude 60 minutes after the maximum amplitude is achieved. It represents fibrinolytic activity. Alternatively, lysis 30 can be used, which assesses fibrinolysis at a shorter time interval.



Chapter 131: Anesthesia Principles and Operating Room Anesthesia Regimens

1. Hepatoxicity is most commonly seen with which of the volatile anesthetic agents?
   A. Enflurane
   B. Halothane

C. Isoflurane

D. Sevoflurane

Preferred response: B

Rationale

In addition to the parent compound, metabolic products may be responsible for the toxicity of the potent inhalational anesthetic agents. Fifteen to 20% of halothane is metabolized compared with 5% to 10% for sevoflurane, 2% to 3% for enflurane, 0.2% for isoflurane, and less than 0.1% for desflurane. The mechanism of hepatotoxicity relates to the metabolic product, TFA or trifluoroacetic acid, acting as a hapten that binds to hepatocytes and induces an immune-mediated hepatitis. Hepatotoxicity can occur following exposure to halothane, enflurane, isoflurane, or desflurane. TFA is not produced during sevoflurane metabolism as its metabolism is via a different pathway. Given the limited metabolism of enflurane, isoflurane, and desflurane, the risk of hepatotoxicity is extremely low. Risk factors for halothane-hepatitis include prior anesthetic exposure, female gender, age ≥35 years, and obesity.

2. Which of the following anesthetic agents or metabolite may impair vitamin B_{12} metabolism?

A. Halothane

B. Ketamine

C. Nitrous oxide

D. Propofol

Preferred response: C

Rationale

When used for procedural sedation on repeated occasions, nitrous oxide impairs vitamin B_{12} metabolism through inactivation of methionine synthetase. This may lead to bone marrow impairment with megaloblastic anemia and deterioration of the posterior columns of the spinal cord and neurologic impairment. These effects may occur not only in patients but also in health care workers with chronic exposure, thereby mandating effective scavenging of exhaled gases to avoid environmental pollution whenever nitrous oxide is administered.

3. Which of the following agents may increase intracranial pressure (ICP)?

A. Morphine

B. Propofol

C. Sevoflurane

D. Thiopental

Preferred response: C

Rationale

Barbiturates (eg, thiopental and thiamylal) and propofol decrease the cerebral metabolic rate for oxygen, resulting in reflex cerebral vasoconstriction and a decrease

in cerebral blood volume, thus decreasing the ICP. Morphine has no effect on cerebral dynamics. All of the inhalational anesthetic agents, including sevoflurane, result in nonspecific cerebral vasodilatation, which increases ICP in patients with altered intracranial compliance. The effect of the inhalational anesthetic agents can be partially blunted with hyperventilation.

4. Malignant hyperthermia (MH) may be triggered by which of the following agents?
   A. Etomidate
   B. Ketamine
   C. Propofol
   D. Succinylcholine
   Preferred response: D

Rationale

MH is an inherited disorder of muscle metabolism affecting the calcium channel, whereby there is ongoing activation of the channel with increases in intracellular calcium concentrations and increased muscle metabolism. This phenomenon results in hypercarbia, hyperthermia, acidosis, and rhabdomyolysis with hyperkalemia. MH can be triggered by succinylcholine or any of the inhalational anesthetic agents. Treatment is removal of the offending agent, symptomatic therapy directed against metabolic derangements, and dantrolene to block ongoing calcium release.

5. Which of the following is the least potent anesthetic, that is, has the highest minimum alveolar concentration (MAC)?
   A. Desflurane
   B. Halothane
   C. Isoflurane
   D. Nitrous oxide
   Preferred response: D

Rationale

MAC is a judge of the potency of an inhalational anesthetic agent. It describes the expired concentration of the agent required to prevent movement in 50% of patients in response to a surgical stimulus (ie, incision). Nitrous oxide has a MAC of greater than 100% and is therefore the least potent of the inhalational anesthetic agents.

6. Negative chronotropic effects are most likely with which agent?
   A. Desflurane
   B. Isoflurane
   C. Nitrous oxide
   D. Sevoflurane
   Preferred response: D

Rationale

All of the inhalational anesthetic agents can have adverse hemodynamic effects.

These are generally minimal with nitrous oxide and vary depending on the potent inhalational anesthetic agent used. Desflurane and isoflurane generally result in vasodilation, which results in reflex tachycardia. Sevoflurane has some direct negative chronotropic effects and therefore may result in a slowing of the heart rate.

Chapter 132: Malignant Hyperthermia

1. Muscular stiffness that persists after complete blockade of neuromuscular transmission produced by a competitive neuromuscular blocker such as rocuronium is MOST LIKELY due to:

   A. Brody's disease

   B. Malignant hyperthermia

   C. Sepsis

   D. Status epilepticus

   Preferred response: B

Rationale

Deep neuromuscular block with rocuronium will produce flaccidity if rigidity were a result of seizures or rigors with sepsis. Both Brody's disease and myotonia can produce rigidity that would NOT be relieved by blockade of neuromuscular transmission, but these are MUCH less common than defects of the ryanodine receptor type 1, which can result in malignant hyperthermia.

2. The most common side effect of IV dantrolene is:

   A. Failure to decrease temperature from >40.5°C to <38°C

   B. Hepatitis

   C. Hyperkalemic cardiac arrest

   D. Muscle weakness

   Preferred response: D

Rationale

Muscle weakness is an expected pharmacologic result of dantrolene in normal and abnormal muscle. Approximately 25% of people who receive IV dantrolene in doses of 2.5 mg/kg or more experience subjective weakness. Airway support and positive pressure ventilation may be required after administration of high doses of dantrolene. However, there have been cases of fulminant malignant hyperthermia (MH) in which treatment with dantrolene was started so late that rigidity persisted. This is an ominous sign. There should be postmortem testing in such cases to examine the entire ryanodine receptor type 1 gene.

Phlebitis has occurred in about 10% to 15% of people who received IV dantrolene. To decrease the chance of severe phlebitis requiring prolonged treatment, dantrolene should be carefully diluted as recommended by the manufacturer and administered

in a large or preferably central vein, if feasible.

Hepatitis is extremely rare with acute administration of dantrolene. It has been reported infrequently after chronic administration of oral dantrolene to treat spasticity. During acute, fulminant MH, hepatic enzymes may rise without hepatic injury because these enzymes also originate from injured muscle.

Failure to decrease critical temperature can occur with use of dantrolene, but usually this is because dantrolene dosing was not repeated quickly enough or because dantrolene extravasated and was therefore not effective. Dantrolene usually reduces temperature in patients with normal muscle, as well as those experiencing an MH crisis. Rapid, repeated dosing of 2.5 mg/kg of dantrolene usually results in normalization of the increased metabolism and hyperthermia in MH. As noted above, metabolic abnormalities can be reversed if treatment is delayed, but rigidity may persist and the patient may die of complications of MH.

Hyperkalemic cardiac arrest may occur during treatment with dantrolene because of the severity of the MH episode and consequent muscle damage. There has been controversy regarding possible drug interactions with dantrolene that may produce or exacerbate hyperkalemia. But evidence to support the occurrence of hyperkalemia when dantrolene is given to patients receiving calcium channel blockers is lacking.

3. Blood-based genetic testing to evaluate risk of malignant hyperthermia (MH) is the most useful next action to take when:
   - A. An MH causative change in the ryanodine receptor type 1 gene was previously identified in a blood relative.
   - B. MH is suspected during anesthesia.
   - C. There is a suspicion of an MH reaction in a grandparent of the patient.
   - D. The patient has been diagnosed with muscular dystrophy.

   Preferred response: A

Rationale

When a first-degree relative is known to have an MH causative mutation, the patient should have that exon of the ryanodine receptor type 1 gene (RYR1) examined as the first step in assessing his or her risk of developing MH. Half of the patient's relatives are likely to be identified as having an increased risk of MH. This is important for their risks of heat-related illness, sudden death, and statin myopathy. Examination of ONE EXON of RYR1 can be performed at several different genetic laboratories.

Often when MH is suspected during anesthesia, the anesthesiologist will discontinue the inhalation anesthetics and start treatment for MH before the signs of MH become severe. This course of action is ideal for the safety of the patient; however, a large percentage of the patients treated for MH who did not have high Clinical Grading Scores (see Larach, 1994, Anesthesiology) are likely to have normal results on the specialized muscle bioassay that is highly sensitive for the diagnosis of MH susceptibility, the caffeine-halothane muscle contracture test (CHCT). Ideally, the patient who received an anesthetic and was suspected of developing MH should be evaluated at an MH Diagnostic Testing Center. See www.mhaus.org/testing for the contact information for active testing centers. Only the CHCT can produce a secure diagnosis of NOT being at increased risk of MH.

When there is a family history of suspected MH, the family tree and all the

medical and anesthetic records should be evaluated. The individual who has the most evidence of increased MH risk should have muscle contracture testing first. Unfortunately, many families will not follow this course. It is cheaper and less trouble to obtain a comprehensive test of all of the three genes most often associated with MH. However, the results of this exam are difficult to interpret unless a known causative MH mutation is found.

If the patient has muscular dystrophy there may be an associated dysfunction of the ryanodine receptor channel, but it is unlikely that there is a mutation in this channel unless the patient has been diagnosed with central core disease or a less common congenital myopathy. Not all congenital myopathies are related to RYR1.

4. The earliest sign of malignant hyperthermia (MH) is which of the following?

A. Hypoxia

B. Hyperthermia

C. Hypercarbia

D. Masseter spasm

Preferred response: C

Rationale

The initial signs of an episode of MH are nonspecific. Hypercarbia is the earliest sign of MH. Tachycardia and dysrhythmias may also occur early in the course of an episode of MH. Mottled cyanosis of the skin and generalized muscle rigidity may be present. Masseter spasm has been claimed to be an early sign of MH. Later, temperature elevation occurs.

5. The pathophysiologic mechanism responsible for the manifestations of malignant hyperthermia (MH) is which of the following?

A. Excessive serotoninergic activity at 5-HT1A receptors

B. Excessive stimulation of α-adrenergic receptor

C. Increase in sarcoplasmic sodium concentration

D. Increase in sarcoplasmic calcium concentration

Preferred response: D

Rationale

MH is a clinically heterogeneous disorder in which a marked increase in the metabolic rate of genetically abnormal muscle can result in destruction of the muscle and multiorgan system failure. The underlying biochemical defect is a sudden increase in the concentration of calcium ion in the sarcoplasm. An increased metabolic rate of muscle produces a load of acid sufficient to overwhelm the buffering capacity of the body and the ability of the lungs to excrete carbon dioxide. Increased oxygen demand and the concomitant sympathetic response challenge the cardiovascular system.

Neuroleptic malignant syndrome (NMS) resembles MH in clinical findings, with the exception that the time course of NMS is over hours to days rather than minutes to hours. NMS occurs only in association with a pharmacologic trigger or potent neuroleptic agents. NMS is related to the blockade of dopamine receptors. The

dopamine antagonist bromocriptine has been used successfully to treat this disorder.

The serotonin syndrome is caused by excessive serotoninergic activity at the 5-HT1A receptors in the central nervous syndrome. The symptoms of serotonin syndrome include rapid onset of cognitive and behavioral changes, autonomic dysfunction, and neuromuscular abnormalities. Fever can be extreme.

6. Which of the following tests is most likely to be helpful in evaluating for the presence of malignant hyperthermia (MH)?

   A. Arterial lactate

   B. Elevation of creatine phosphokinase

   C. Elevation of myoglobin

   D. Venous blood gas

   Preferred response: D

Rationale

The test that is most likely to be helpful in assessing the presence of MH is venous blood gas analysis. Elevated carbon dioxide (CO_2) tension is apparent in mixed venous blood before it is abnormal in arterial blood during an episode of MH. An increase in lactate release from muscle occurs before a decrease in the partial pressure of oxygen in venous blood is observed during an episode of MH. If venous blood indicates significant acidosis, partial pressure of CO_2 greater than 60 torr, and bicarbonate less than 19 mEq/L and the history of the patient is consistent with MH, the physician may assume that the patient is experiencing an episode of MH and treat the patient accordingly.

7. Which of the following drugs can cause hyperkalemia and myocardial depression when given to a patient with malignant hyperthermia (MH) who is being treated with dantrolene?

   A. Calcium channel blockers

   B. Procainamide

   C. Lidocaine

   D. Procainamide

   Preferred response: A

Rationale

Cardiac dysrhythmias may occur with MH but usually stop when the episode is adequately treated with dantrolene. Lidocaine may be administered with the usual precautions. Before lidocaine was accepted as a drug that was unlikely to trigger MH, procainamide was the antidysrhythmic of choice during an episode of MH. Procainamide is no longer recommended for treatment of MH-susceptible patients. Calcium channel blockers are not indicated for patients with MH because they may cause severe hyperkalemia and cardiovascular collapse in the presence of MH.

Chapter 133: Neuromuscular

Blocking Agents

1. Fatal hyperkalemia is an adverse effect of which neuromuscular blocking agent?
   A. Atracurium
   B. Cisatracurium
   C. Pancuronium
   D. Succinylcholine
   Preferred response: D

Rationale

Atracurium, cis-atracurium, curare, and pancuronium are nondepolarizing neuromuscular blocking agents, which act as competitive antagonists at the neuromuscular junction, blocking the effects of acetylcholine at the nicotinic receptor. Succinylcholine is a depolarizing neuromuscular blocking agent. Succinylcholine's mechanism of action is to bind to and activate the acetylcholine receptor. In situations where up-regulation of the receptors has occurred, such as with denervation injury, there are extrajunctional receptors. Succinylcholine is a depolarizing neuromuscular blocking agent. The binding of succinylcholine to these receptors results in opening of cation channels and the release of potassium, which can result in hyperkalemia.

2. The metabolism of which of the following neuromuscular blocking agents results in a potentially epileptogenic metabolite?
   A. Cis-atracurium
   B. Pancuronium
   C. Rocuronium
   D. Vecuronium
   Preferred response: A

Rationale

Cis-atracurium undergoes Hoffman degradation, a nonenzymatic process, which results in the breakdown of cis-atracurium. During this process, laudanosine is released. Although its clinical effects are relatively unknown in man, animal studies suggest that it may lower the seizure threshold.

3. Which neuromuscular blocking agent (NMBA) can be reversed with suggamadex?
   A. Atracurium
   B. Cis-atracurium
   C. Rocuronium
   D. Succinylcholine
   Preferred response: C

Rationale

Reversal of neuromuscular blockade is possible only with nondepolarizing NMBAs. The drugs used to reverse neuromuscular blockade inhibit the enzyme acetylcholinesterase. More acetylcholine is therefore available to compete with the NMBA at the nicotinic receptor of the neuromuscular junction. The commonly used acetylcholinesterase inhibitors or “reversal agents” include neostigmine, pyridostigmine, and edrophonium. Despite a similar mechanism of action, the clinical effects (such as onset and duration) of these agents differ. Neostigmine and pyridostigmine are hydrolyzed by acetylcholinesterase. During this process, the enzyme is carbamylated and inactivated. Edrophonium does not break down the enzyme acetylcholinesterase; rather, it competitively and reversibly inhibits its function.

Sugammadex is a cyclodextrin, and instead of inhibiting the enzyme acetylcholinesterase, it forms a tight 1 : 1 complex with the steroidal neuromuscular blocking agents. It has been shown to rapidly and effectively reverse rocuronium, vecuronium, and perhaps even pancuronium. Because of a limited dissociation rate, the reversal is maintained. Unlike the use of acetylcholinesterase inhibitors, reversal using sugammadex is feasible even with intense blockade, thereby providing the potential for the rapid reversal of neuromuscular blockade in the “cannot intubate—cannot ventilate” scenario. Future studies are needed to fully evaluate this medication in the pediatric population.

4. Which of the following neuromuscular blocking agents causes initial bradycardia and hypotension, followed by tachycardia and hypertension?
   A. Atracurium
   B. Pancuronium
   C. Succinylcholine
   D. Vecuronium
   Preferred response: C

Rationale

Succinylcholine can have profound cardiovascular effects. Typically, intravenous succinylcholine produces initial bradycardia and hypotension, followed after 15 to 30 seconds by tachycardia and hypertension.

5. With respect to use of succinylcholine in infants and children and in adults, which of the following statements is true?
   A. Children have a slower clearance of succinylcholine compared with adults.
   B. Hyperkalemia resulting from succinylcholine administration is more common in adults compared with children.
   C. Neonates and infants require higher doses of succinylcholine on the basis of weight than do older children and adults to produce apnea.
   D. Myoglobinemia from succinylcholine administration is more common in adults compared with children.
   Preferred response: C

Rationale

Succinylcholine is a rapid-acting depolarizing muscle relaxant of ultrashort duration. Succinylcholine is metabolized by butyrylcholinesterase. Markedly prolonged neuromuscular blockade can result from atypical or abnormally low enzyme concentrations. When differences in volume of distribution and concentration of anesthesia are taken into account, infants and small children appear relatively resistant to succinylcholine, have faster clearance, and have a shorter onset time (at equal multiples of ED95—the mean dose that produces a maximal effect of 95% twitch suppression for a given drug).

Neonates and infants require about twice as much succinylcholine on the basis of weight than do older children or adults to depress respiration or neuromuscular transmission or to produce apnea.

Adverse effects of succinylcholine include dysrhythmias, increased intraocular pressure, prolonged apnea, injured muscle membranes with associated hyperkalemia, association with masseter spasm, and malignant hyperthermia and death. Infants and small children have a high incidence of such complications. In infants and small children, profound sustained sinus bradycardia (rates of 50 to 60 beats/minute) is frequently observed; rarely, asystole occurs.

Because of limited muscle mass, the infant or small child, in contrast to the adult, seldom has strong fasciculations with the use of succinylcholine.

In healthy patients, succinylcholine increases plasma levels of potassium by 0.3 to 0.5 mEq/L. Alarming concentrations of potassium, as high as 11 mEq/L, along with cardiovascular collapse, have been frequently reported with succinylcholine in a variety of conditions, including burns, massive trauma, stroke, spinal cord injury, and muscle disease. Strong fasciculations are not necessary to produce hyperkalemia in susceptible patients. No data exist to suggest that the infant is any less vulnerable than the adult to massive potassium flux from the listed conditions.

A high incidence of myoglobinemia occurs after the administration of succinylcholine in prepubertal patients, especially those anesthetized with halothane. Myoglobinemia rarely results from succinylcholine administration in adults.

6. Which of the following NMBAs is metabolized in the liver?

A. Atracurium

B. Cisatracurium

C. Succinylcholine

D. Vecuronium

Preferred response: D

Rationale

Nondepolarizing muscle relaxants have four routes of elimination: renal excretion, hepatic excretion, biotransformation (including Hofmann elimination), and tissue binding.

TABLE Q133.6

Elimination Routes of Muscle Relaxants

Hepatobiliary Agent	Metabolism in Plasma	Uptake and Metabolism	Renal Excretion
Mivacurium	XX		
Atracurium	XX		
Cisatracurium	XX		
Vecuronium		XX	
Rocuronium		XX	X
Pancuronium		XX	X
Pipecuronium		XX	X
Doxacurium			XX

X, Alternative route; XX, major route.

Hepatic uptake and storage of steroidal nondepolarizing muscle relaxants (pancuronium and especially vecuronium) represent another aspect of drug distribution. The large hepatic uptake of vecuronium may be the cause of its short duration of action.

7. Prolonged paralysis most commonly results in children who have renal failure when which of the following NMBAs is used?

A. Atracurium

B. Cisatracurium

C. Pancuronium

D. Succinylcholine

Preferred response: C

Rationale

If given to a person in renal failure, pancuronium may cause prolonged paralysis. The clearance of pancuronium is reduced by one-half to two-thirds, whereas the volume of distribution is only minimally affected. The metabolites accumulate in persons with renal failure because they normally depend on renal excretion. The metabolites, especially 3-hydroxypancuronium, have some neuromuscular blocking activity and further prolong paralysis.

Atracurium does not depend on the kidney or liver for elimination because it is degraded by Hofmann elimination and ester hydrolysis. Because atracurium does not depend on the kidneys for excretion, its elimination half-life and duration of action are not prolonged in patients with renal failure. Laudanosine is the major end-product of atracurium degradation. The byproducts of atracurium metabolism have no neuromuscular blocking effect.

Cisatracurium is seemingly primarily degraded by Hofmann elimination. Renal failure or liver disease has a minimal effect on the pharmacodynamics of cisatracurium.

Mivacurium is metabolized by butyrylcholinesterase in the plasma. It is not cleared by either the kidneys or liver. In adults with renal or hepatic failure and subsequently reduced butyrylcholinesterase activity, the duration of mivacurium-induced neuromuscular blockade is increased by renal and hepatic failure. Similar studies have not been performed in children.

Chapter 134: Sedation and Analgesia

1. Which of the following opiates is metabolized to a more toxic drug?

A. Codeine

B. Fentanyl

C. Meperidine

D. Remifentanil

Preferred response: C

Rationale

Meperidine is metabolized by the liver to normeperidine, which is twice as toxic as meperidine and has a longer half-life ($T_{1/2}$) (15 hours). Normeperidine accumulation is enhanced in patients with an induced cytochrome P-450 system.

2. Which of the following drugs is the most potent opioid in clinical practice?

A. Alfentanil

B. Fentanyl

C. Hydromorphone

D. Sufentanil

Preferred response: D

Rationale

Hydromorphone is seven times as potent as morphine. Morphine is 100 times less potent than fentanyl. Sufentanil is 5 to 10 times more potent than fentanyl and is the most potent opioid in clinical practice, posing a high risk of apnea with bolus administration. Alfentanil is five times less potent than fentanyl.

3. Which of the following opioids has the shortest elimination $T_{1/2}$?

A. Fentanyl

B. Meperidine

C. Morphine

D. Remifentanil

Preferred response: D

Rationale

The half-lives of the aforementioned opioids are as follows: alfentanil, 90 minutes; fentanyl, 4 hours; morphine, 2 hours (longer in younger children); meperidine, 15 hours; and remifentanil, 8 minutes.

4. Which of the following opioids does not require a bolus dosing to achieve a rapid change in effect when given as a continuous infusion?

A. Alfentanil

B. Fentanyl

C. Morphine

D. Remifentanil

Preferred response: D

Rationale

Sedation with remifentanil can be effectively managed by continuous infusion without the need for a bolus because of the short $T_{1/2}$. An increase or decrease of infusion rate is rapidly reflected by a change in the degree of sedation, which is important to note. Most other opiate sedatives require bolus dosing to achieve a rapid change in effect. Bolus dosing is neither appropriate nor needed for remifentanil.

5. Compared with morphine, which of the following statements is true about methadone?

   A. It has inactive metabolites.

   B. It is an ineffective analgesic.

   C. It is more sedating.

   D. It is more potent.

   Preferred response: A

Rationale

Methadone has an oral bioavailability of 80% to 90% and an elimination $T_{1/2}$ of 12 to 24 hours. It is equipotent to morphine. Methadone has inactive metabolites and is less sedating than morphine while remaining an effective analgesic. Because of its higher bioavailability and reduced first-pass metabolism, it is more predictable orally than is morphine. It has been extensively used in the outpatient management of patients addicted to opiates.

6. Which of the following opiate receptors is responsible for the respiratory depression seen with morphine?

   A. delta (δ)

   B. kappa (κ)

   C. mu_1 (μ_1)

   D. mu_2 (μ_2)

   Preferred response: D

Rationale

Opioids are agonists at various opioid receptors, for which several endogenous ligands exist. Three major classes of receptors exist: mu (μ), kappa (κ), and delta (δ). The opioid receptors possess the same general structure of an extracellular N-terminal region, seven transmembrane domains, and an intracellular C-terminal tail structure. Subtypes of each receptor (eg, μ_1, μ_2) exist, as do less well-characterized opioid receptors δ, κ, and σ. Most of the therapeutic and adverse effects can be accounted for by agonist activity at the μ receptor, which is responsible for analgesia, respiratory depression, pupillary constriction, and euphoria.

TABLE Q134.6

Classification of Opiate Receptors and Subtypes

Subtype	Prototypic Drugs	Actions
μ_1	Opiates and most opiate peptides	Supraspinal analgesia including periaqueductal gray matter, nucleus raphe magnus, and locus coeruleus
		Prolactin release
		Acetylcholine turnover in brain
		Catalepsy
μ_2	Morphine	Respiratory depression
		Dopamine turnover in brain
		Gastrointestinal tract transit
		Most cardiovascular effects
δ	Enkephalins	Spinal analgesia
		Dopamine turnover
κ	Dynorphin	Spinal analgesia
		Inhibition of antidiuretic hormone
		Sedation
σ	N-allynormetazocine	Psychotomimetic effects

Modified from Baresh PG, Cullen BF, Stoelting RK, et al. eds. Clinical Anesthesia. 2nd ed. Philadelphia: JB Lippincott; 1992.

7. Which of the following opiates has an active metabolite with a higher potency than the agonist itself?

   A. Codeine

   B. Fentanyl

   C. Meperidine

   D. Morphine

   Preferred response: D

Rationale

Morphine is metabolized to morphine-3-glucuronide (M3G) and M6G in the liver. M3G is the major metabolite and has little morphine-like activity, although some research has suggested that M3G may be associated with an antinociceptive effect, accounting for failure of analgesia during long-term use. In contrast, M6G is many times more potent than morphine itself. Morphine undergoes significant first-pass hepatic metabolism, whereby after a single parenteral dose, only morphine is initially active. After a single dose by mouth, both morphine and M6G are active. With long-term oral use, M6G accumulates until its analgesic effect is greater than that of morphine. A similar effect can be anticipated with long-term morphine infusion in the patient in the pediatric ICU (PICU).

8. Which of the following options displays the correct order of potency, from most to least potent?

   A. Fentanyl > sufentanil > morphine > meperidine

   B. Fentanyl > morphine > meperidine > sufentanil

   C. Morphine > meperidine > fentanyl > sufentanil

   D. Sufentanil > fentanyl > morphine > meperidine

   Preferred response: D

Rationale

Sufentanil is 5 to 10 times more potent than fentanyl and is the most potent opioid used in clinical practice. Fentanyl is 100 times more potent than morphine.

Meperidine has one-tenth the potency of morphine. Relative drug potency is summarized as follows:

TABLE Q134.8

Relative Drug Potency

Drug	Relative Potency
Morphine	1
Meperidine	0.1
Methadone	1
Hydromorphone	7
Alfentanil	10
Fentanyl	100
Sufentanil	500

9. Compared with fentanyl, alfentanil has which of the following?

A. Higher potency

B. Longer elimination $T_{½}$

C. More prolonged onset of action

D. Shorter duration of action

Preferred response: D

Rationale

Alfentanil is 5 times less potent than fentanyl. Although it is less lipid soluble than fentanyl because of its low pKa (negative logarithm of the acid ionization constant), a higher percentage of the drug is present in the active un-ionized form, which results in a rapid onset. Because of its low volume of distribution, alfentanil has a short elimination $T_{½}$, which results in a short duration of action (5 to 10 minutes).

10. Which of the following sedatives is known to have negative inotropy and chronotropy properties in critically ill patients?

A. Diazepam

B. Fentanyl

C. Lorazepam

D. Midazolam

Preferred response: D

Rationale

Benzodiazepines (BZDs) have few cardiovascular adverse effects, but in a sick, intensive care population, profound cardiovascular depression may occasionally be observed. BZDs should be used judiciously until the patient response is known. Midazolam has been most often associated with this effect, and research in dogs has shown both negative inotropy and chronotropy, especially when the sympathetic response has been abolished.

11. Which of the following statements regarding benzodiazepines is correct?

A. Midazolam has a longer $T_{½}$ than lorazepam.

B. The elimination $T_{½}$ of lorazepam is 14 hours.

C. Lorazepam is metabolized by the cytochrome P-450 system.

D. Midazolam toxicity is related to propylene glycol.

Preferred response: B

Rationale

Diazepam is highly lipid soluble with a long $T_{½}$ (24 hours). Metabolism by oxidative biotransformation generates several hypnotically active metabolites with an elimination $T_{½}$ that may be longer than diazepam including oxazepam ($T_{½}$, 10 hours) and *N*-dimethyldiazepam ($T_{½}$, 93 hours).

Lorazepam produces sedation for 4 to 8 hours after a single dose. It has a slower onset than midazolam. The elimination $T_{½}$ is about 14 hours. Metabolism is by glucuronyl transferase, not the cytochrome P-450, and there are no active metabolites. Lorazepam for intravenous use has propylene glycol as a carrier. There is a risk of a metabolic lactic acidosis because of the metabolism of this carrier. Cases of fatal metabolic acidosis from propylene glycol have been reported in neonates taking a particular vitamin preparation.

Midazolam has a short elimination $T_{½}$ of 2 hours.

12. In which situation is use of flumazenil contraindicated?

A. Recovery from conscious sedation with midazolam

B. Respiratory depression with use of benzodiazepine

C. Treatment of paradoxical reaction to midazolam

D. Tricyclic antidepressant overdose

Preferred response: D

Rationale

Flumazenil is indicated for the complete or partial reversal of the central sedative effects of benzodiazepines (BZDs). Contraindications include patients who have a known hypersensitivity to BZDs, patients with epilepsy who are receiving BZD treatment, and those who have overdosed with a tricyclic antidepressant. The use of flumazenil is often associated with mild to moderate tachycardia and hypertension.

In cases of multiple drug overdose, the use of flumazenil remains controversial. It is often overused in the emergency setting without due concern for potential adverse reactions because of the potential toxic effects (cardiac arrhythmias or convulsions) of other psychotropic drugs ingested. The toxicity of tricyclic antidepressants becomes apparent as the effects of BZDs are antagonized. Patients should be evaluated for the signs and symptoms of a tricyclic antidepressant overdose, and an electrocardiogram may be helpful in determining the risks involved.

13. After receiving an overdose of a certain sedative, ataxia and lethargy develop in a 3-year-old girl. She progresses to a comatose state 2 hours after the overdose. Over the course of the day, supraventricular tachycardia and severe hemorrhagic gastritis also develop. Which sedative was probably misused in this case?

A. Chloral hydrate

B. Droperidol

C. Lorazepam

D. Midazolam

Preferred response: A

Rationale

This child probably received an overdose of chloral hydrate. After absorption in the gastrointestinal tract, chloral hydrate is immediately converted into the active component, trichloroethanol, by alcohol dehydrogenase. Trichloroethanol undergoes glucuronidation with some oxidation to trichloroacetate. Trichloroacetate's actions include central nervous system depression with drowsiness and sleep in less than an hour. With an overdose, the patient falls into a deep stupor or coma, and the pupils change from contracted to dilated. At therapeutic levels, the blood pressure and respiratory rate are unaffected. Chloral hydrate has several effects on the cardiovascular system including decreased myocardial contractility, a shortened refractory period, and an increased sensitivity of the heart to catecholamines. It also has effects on mucous membranes. Irritation can cause gastritis, nausea, and vomiting. In cases of overdose, a severe hemorrhagic gastritis with gastric necrosis and esophagitis has been described.

Chloral hydrate overdose produces a clinical picture that is similar to that of acute barbiturate poisoning. Ataxia, lethargy, and coma occur within 1 to 2 hours. In addition, a pearlike odor may be noted. Cardiovascular instability poses the main threat to life. Severe arrhythmias including atrial fibrillation, supraventricular tachyarrhythmia, ventricular tachyarrhythmia, torsades de pointes, and ventricular fibrillation have been described.

14. Which of the following is an adverse effect of haloperidol?

A. Bradycardia

B. Extrapyramidal signs

C. Hypotension

D. Vomiting

Preferred response: B

Rationale

Haloperidol is a potent antipsychotic agent with a nonspecific dopamine antagonist action. It has little effect on the cardiovascular or respiratory systems. It produces the appearance of calm with minimal hypnotic effect and reduces operant behavior (purposeful movement). The patient appears tranquil and dissociated from his or her surroundings but is readily accessible if spoken to. Haloperidol may mask actual feelings of mental restlessness. It is a potent antiemetic agent (with action at the chemotrigger zone) and has no appreciable effect on the electroencephalogram. It potentiates analgesics and other sedative agents. Compared with less potent butyrophenones, it has fewer adverse effects. Neuroleptanalgesia, a dissociative form of anesthesia, can be induced when haloperidol is combined with high-dose

opiates. This anesthetic state is useful for certain cardiac and neurosurgical procedures that require cardiovascular stability and a responsive patient. It is metabolized to inactive compounds with a $T_{½}$ of 15 to 25 hours. It is highly protein bound. Hepatic dysfunction increases the $T_{½}$ because of reduced clearance. Adverse effects include extrapyramidal signs, although acute dystonia is rare. Prolongation of the QT interval is possible with the subsequent risk of ventricular tachycardia. Hepatic toxicity can occur but is rare.

Scenario

A 13-year-old patient with spastic quadriplegia is admitted to the PICU in respiratory distress due to aspiration pneumonia. He requires tracheal intubation and mechanical ventilation. The medications he takes at home include antiepileptic drugs (valproic acid, phenobarbital, and carbamazepine) via his gastrostomy tube and baclofen through a pump. On the third day of admission, the following manifestations develop: pruritus, hyperthermia, increased spasticity, and seizures lasting 15 minutes. Laboratory evaluation reveals a creatine phosphokinase level of 5200 IU/L.

15. What is the most probable cause of these manifestations?

A. Baclofen pump malfunction

B. Carbamazepine overdose

C. Malignant hyperthermia

D. Neuroleptic malignant syndrome

Preferred response: A

Rationale

The intrathecal baclofen (ITB) withdrawal syndrome is interesting because it appears to have many similarities with the neuroleptic malignant syndrome. Prolonged muscle contraction caused by rebound spasticity results in thermogenesis, hyperthermia, and rhabdomyolysis. Patients with ITB withdrawal are often managed initially as if they have sepsis and multisystem organ failure, with broad-spectrum antibiotics providing no improvement in the clinical situation; this results in a delay of the diagnosis of ITB withdrawal. The differential diagnosis of the hypermetabolic state is listed in the box below. The symptoms of ITB withdrawal can be classified into three categories (see Table Q134.15). Often the first clinical signs are the development of itching and some increase in spasticity. If replacement baclofen is not given, then the symptoms may progress to a severe hypermetabolic state that can be fatal if the cause is not recognized and treated.

TABLE Q134.15

Severity of ITB Withdrawal

Designation	Description
Mild	Pruritic symptoms and increased spasticity
Moderate	High fever, altered mental status, seizures and profound rigidity, autonomic instability
Severe	Rhabdomyolysis, hepatic, renal failure, disseminated intravascular coagulation, brain injury, death

16. What is the next step in managing the patient described in the scenario?

A. Administering a benzodiazepine

B. Administering dantrolene

C. Administering vecuronium

D. Discontinuing carbamazepine

Preferred response: A

Rationale

Although the primary aim should be to replace baclofen, rapid replacement of ITB may not be possible. The required oral baclofen replacement dose may be 50 to 100 times the intrathecal dose, and this dose is often not well tolerated by the patient because of adverse effects. An IV dose of benzodiazepine should be the initial step in the treatment of baclofen withdrawal. Dantrolene has been used as an adjunct therapy for the increased spasticity. The use of the potent serotonin antagonist cyproheptadine has been proposed as an alternative treatment adjunct. It improved fever, spasticity, and itching in adult patients with gout who had ITB withdrawal.

17. Use of dexmedetomidine should be avoided in patients who are also receiving which one of the following medications?

A. Albuterol

B. β-blockers

C. Insulin

D. Methylprednisolone

Preferred response: B

Rationale

Dexmedetomidine is contraindicated in patients with heart block, and bradycardia has been reported in an infant treated with digoxin who received dexmedetomidine during the infusion phase. It also would appear prudent to avoid its use with other drugs that can reduce arteriovenous node function, such as β-blockers and calcium channel blockers and with patients with severe ventricular dysfunction or hypovolemia, because reduction in sympathetic tone may cause a profound decrease in blood pressure.

18. Which of the following inhalational agents is most widely used in ICUs because of its safety profile?

A. Desflurane

B. Enflurane

C. Halothane

D. Isoflurane

Preferred response: D

Rationale

The use of inhalational agents in the PICU involves the use of equipment that may

be unfamiliar to pediatric intensive care physicians. Isoflurane appears to be the best choice and it offers several useful advantages, including the ability to deeply sedate patients (especially those who are difficult to sedate) without polypharmacy. Although they are poorly defined at present, tolerance and a withdrawal-like syndrome have been described; however, they appear to occur more slowly than with other sedative agents.

Multiple case reports of the use of inhalational agents for status asthmaticus in both adults and children have been published. Because of its speed of onset and its bronchodilation effects, isoflurane is a useful adjunct to α_2-adrenergic agonists. If no improvement occurs, or if unacceptable adverse effects occur, then its effects rapidly wane on discontinuation. Isoflurane is recommended for use because of its safer adverse effect profile. No reports have been made of renal or hepatic dysfunction despite use of isoflurane for prolonged periods. Hypotension seems to be more common in patients receiving isoflurane; it is possibly related to increased intrathoracic pressure and the potential for greater preload reduction with vasodilation. Fluid boluses are often required, and occasionally vasopressors are required as well. Because isoflurane is not an analgesic agent, opiates may need to be administered for painful or uncomfortable procedures. In addition, when the patient is weaned off the isoflurane, additional sedatives will be required.

Chapter 135: Tolerance, Withdrawal, and Dependency

---

1. Prolongation of the QT interval has been reported with which of the following drugs?
   A. Dexmedetomidine
   B. Lorazepam
   C. Methadone
   D. Midazolam
   Preferred response: C

Rationale

Concerns of QT prolongation have been released with the use of methadone maintenance in the treatment of adults with drug addiction. The first concerns surfaced when increased mortality was noted in this population. While a causal link has not been established, electrocardiographic screening during methadone use in adults is performed to identify QT prolongation and arrhythmias. To date, there are no reports from the pediatric population; however, these concerns have led to the consideration of obtaining periodic ECGs before and after instituting therapy with methadone. Given the multitude of medications used in the pediatric ICU patient, avoidance of interactions with other agents that can potentially prolong the QT interval is suggested. A final issue with methadone is its metabolism by the P-450 isoenzyme system of the liver, making alterations in metabolism possible on the basis of genetic factors and coadministration of other medications. These factors

should be considered when methadone is started or other medications are added to the patient's regimen.

2. Which of the following is a predominant clinical finding with dexmedetomidine withdrawal?

   A. Bradycardia

   B. Emesis

   C. Hypertension

   D. Miosis

   Preferred response: C

Rationale

Dexmedetomidine is a centrally acting α_2-adrenergic agonist that decreases central sympathetic outflow. Clinical effects include not only sedation but also a slowing of heart rate and a lowering of blood pressure. With abrupt discontinuation following its prolonged administration, activation of the sympathetic nervous system occurs with tachycardia and hypertension. Similar clinical findings have been reported with the abrupt withdrawal of clonidine.

Chapter 136: Pediatric Delirium

---

1. Delirium cannot be diagnosed in the presence of:

   A. Coma

   B. Infancy

   C. Sedation

   D. Significant developmental delay

   Preferred response: A

Rationale

Delirium can be reliably diagnosed in nearly all children. With attention to developmental stage, delirium can be diagnosed in infancy. With establishment of alteration from the child's neurologic baseline, delirium can be diagnosed in children with developmental delay. Children who are mechanically ventilated and/or sedated can be assessed for delirium as well, as long as they are arousable to verbal stimulation and not in a coma.

2. Which of the following is NOT a risk factor for delirium in children?

   A. Developmental delay

   B. Increased severity of illness

   C. Infancy

   D. Invasive mechanical ventilation

   Preferred response: C

Rationale

Children at increased risk for developing delirium when critically ill include those with higher severity of illness, those requiring invasive mechanical ventilation, those with baseline developmental delay, and those between the ages of 2 and 5 years. Infants are not at increased risk for developing delirium when compared with children older than 2 years of age.
